Adequate nutrition in essential for brain growth and development, especially during the first 1,000 days of life — a critical period of development for all organs and systems spanning from conception to 24 months of age (52). Animal studies have established that zinc deficiency in early life interferes with normal brain development and cognitive functions (reviewed in 53). Data on the effect of zinc supplementation during pregnancy on infants' neurologic and psychomotor outcomes is very limited. In a randomized, placebo-controlled trial in African-American women, daily maternal supplementation with 25 mg of zinc from about 19 weeks' gestation had no effect on neurologic development test scores in their children at five years of age (54).

Several studies have reported on the effect of postnatal zinc supplementation on mental and motor development. Two early randomized controlled trials, one conducted in India and the other in Guatemala, suggested that postnatal supplementation with 10 mg/day of zinc resulted in toddlers being more vigorous (55) and functionally active (56). In one trial conducted in Brazilian newborns from low-income families and weighing between 1,500 g and 2,499 g at birth, neither zinc supplementation for eight weeks with 1 mg/day or 5 mg/day improved mental and psychomotor development at 6 or 12 months of age compared to a placebo and assessed using the Bayley Scales of Infant Development (BSID) for Mental Development Index (MDI) and Psychomotor Development Index (PDI) (57). Additionally, a randomized, placebo-controlled, double-blind trial in Chilean newborns (birth weights >2,300 g) from low-income families reported no effect of zinc supplementation (5 mg/day) on mental and psychomotor development indices at 6 and 12 months (58). Two other trials found that supplemental zinc failed to improve MDI or PDI at 12 months of age when zinc (10 mg/day) was given to six-month-old infants for six months (59) or at the end of the intervention in toddlers aged 12-18 months when zinc (30 mg/day) was given for four months (60). A 2012 Cochrane review of eight clinical trials found no evidence that postnatal zinc supplementation improves mental or motor development of infants and children from populations with presumably inadequate zinc status (61).

Impaired immune system function

Adequate zinc intake is essential in maintaining the integrity of the immune system (62), specifically for normal development and function of cells that mediate both innate (neutrophils, macrophages, and natural killer cells) and adaptive (B-lymphocytes and T-lymphocytes) immune responses (63). Because pathogens also require zinc to thrive and invade, a well-established antimicrobial defense mechanism in the body sequesters free zinc away from microbes (64). Another opposite mechanism consists in intoxicating intracellular microbes within macrophages with excess zinc (65). Through weakening innate and adaptive immune responses, zinc deficiency diminishes the capacity of the body to combat pathogens (63, 64). As a consequence, zinc-deficient individuals experience an increased susceptibility to a variety of infectious agents (66).

Increased susceptibility to infectious disease in children

Diarrhea: Zinc promotes mucosal resistance to infections by supporting the activity of immune cells and the production of antibodies against invading pathogens (63, 64, 67). Therefore, a deficiency in zinc increases the susceptibility to intestinal infections and constitutes a major contributor to diarrheal diseases in children (66). In turn, persistent diarrhea contributes to zinc deficiency and malnutrition (66). Research indicates that zinc deficiency may also potentiate the effects of toxins produced by diarrhea-causing bacteria like *E. coli* (68). It is estimated that diarrheal diseases are responsible for the deaths of about 500,000 children under five years of age annually in low- and middle-income countries (69). Zinc supplementation in combination with oral rehydration therapy has been shown to significantly reduce the duration and severity of acute and persistent childhood diarrhea and to increase survival in a number of randomized controlled trials (70). A 2016 meta-analysis of randomized controlled trials found that zinc supplementation reduced the duration of acute diarrhea by one day in children aged >6 months who presented signs of malnutrition (5 trials; 419 children) (71). However, there was little evidence to suggest that zinc could be as efficacious to reduce the duration of acute diarrheal episodes in children aged <6 months and in well-nourished children aged >6 months. Zinc supplementation also reduced the duration of persistent diarrhea in children by more than half a day (5 trials; 529 children) (71).

The World Health Organization (WHO) and the United Nations Children's Fund (UNICEF) currently recommend supplementing young children with 10 to 20 mg/day of zinc as part of the treatment for acute diarrheal episodes and to prevent further episodes in the two to three months following zinc supplementation (72).

Pneumonia: Pneumonia — caused by lower respiratory tract viral or bacterial infections (LRTIs) — accounts for nearly 1 million deaths among children annually, primarily in low-and middle-income countries (69). Vaccinations against *Haemophilus influenzae* type B, pneumococcus, pertussis (whooping cough), and measles can help prevent pneumonia (73). According to a 2009 WHO report on disease risk factors, zinc deficiency may be responsible for 13% of all LRTI cases, primarily pneumonia and flu cases, in children younger than 5 years (74). Accordingly, a 2016 meta-analysis of six trials found that zinc supplementation in children under 5 years old reduced the risk of pneumonia by 13% (75). However, it remains unclear whether supplemental zinc, in conjunction with antibiotic therapy, is beneficial in the treatment of pneumonia. A recent randomized, placebo-controlled trial conducted in Gambian children who were not zinc deficient failed to show any benefit of zinc supplementation (10 mg/day or 20 mg/day [depending on child's age] for 7 days) given alongside antibiotics in the treatment of severe pneumonia (76). A 2018 meta-analysis of five trials (1,822 participants) found no improvement when zinc was used as an adjunct to antibiotic treatment in children with pneumonia (77). There was, however, evidence that supplemental zinc reduced the risk of pneumonia-related mortality (3 trials; 1,318 participants) (77).

Malaria: Early studies have indicated that zinc supplementation may reduce the incidence of clinical attacks of malaria in children (78). A placebo-controlled trial in preschool-aged children in Papua New Guinea found that zinc supplementation reduced the frequency of health center attendance due to *Plasmodium falciparum* malaria by 38% (79). Additionally, the number of malaria episodes accompanied by high circulating parasite concentrations was reduced by 68%, suggesting that zinc supplementation may be of benefit in preventing more severe episodes of malaria. However, a six-month trial in more than 700 West African children did not find any difference in the frequency or severity of malaria episodes between children supplemented with zinc and those given a placebo (80). Another randomized controlled trial reported that zinc supplementation did not benefit preschool-aged children with acute, uncomplicated malaria (81). There is also little evidence to suggest that zinc supplementation could reduce the risk of malaria-related mortality in children (82). At present, there is not enough evidence to suggest a prophylactic and/or therapeutic role for supplemental zinc in the management of childhood malaria (48). A recent randomized, placebo-controlled trial did not provide clear-cut evidence of a protective effect of zinc (25 mg/day) administered to Tanzanian women during their first gestational trimester until delivery on the risk of placental malaria infection (83).

Age-related decline in immune function

Inadequate zinc status in elderly subjects is not uncommon and is thought to exacerbate the age-related decline in immune function (84). In one study, low serum zinc concentrations in nursing home residents were associated with higher risks of pneumonia and pneumonia-related and all-cause mortality (85). Trials examining the effects of zinc supplementation on immune function in middle-aged and elderly adults have given mixed results (reviewed in 86). Some studies showed mixed or no effects of zinc supplementation on parameters of immune function (87-89). However, zinc supplementation was found to have a positive impact on certain aspects of immune function that are affected by zinc deficiency, such as the decline in T-cell (a type of lymphocyte) function (90). For example, a randomized, placebo-controlled study in adults over 65 years of age found that zinc supplementation (25 mg/day) for three months increased blood concentrations of helper T-cells and cytotoxic T-cells (91). Additionally, a randomized, double-blind, placebo-controlled trial in 101 older adults (aged 50-70 years) with normal blood zinc concentrations showed that zinc supplementation at 15 mg/day for six months improved the helper T-cells/cytotoxic T-cells ratio, which tends to decline with age and is a predictor of survival (92). However, the study also suggested that a dose of 30 mg/day of zinc might reduce the number of B-lymphocytes, which play a central role in humoral immunity. Further, zinc supplementation had no effect on various immune parameters, including markers of inflammation, measures of granulocyte and monocyte phagocytic capacity, or cytokine production by activated monocytes (92).

A more recent trial examined the effect of daily supplementation with a multiple micronutrients, including 5 mg or 30 mg of zinc for three months, on zinc status and markers of immune function in institutionalized elderly participants (mean age, >80 years) with low serum zinc concentrations (93). Zinc status was improved with the 30 mg/day dose — but not with 5 mg/day — yet the most zinc-deficient individuals failed to achieve normal serum zinc concentrations within the intervention period. The number of circulating T-cells was also significantly increased in those who took the micronutrient supplement with the higher versus low dose of zinc (93).

More research is warranted before zinc supplementation could be recommended to older adults, especially those with no symptoms of declining immunity. Nonetheless, the high prevalence of zinc deficiency among institutionalized elderly adults should be addressed and would likely improve the performance of their immune systems (86).

Type 2 diabetes mellitus

There is a close relationship between zinc and insulin action. Specifically, in pancreatic β-cells, zinc is involved in insulin synthesis and storage in secretory vesicles. Zinc is released with the hormone when blood glucose concentrations increase (15). Zinc is also understood to stimulate glucose uptake and metabolism by insulin-sensitive tissues through triggering the intracellular insulin signaling pathway (94). Single-nucleotide polymorphisms (SNPs) in the *SLC30A8* (solute carrier family 30 member 8) gene, coding for a zinc transporter that co-localizes with insulin in β-cells, have been associated with higher risks of type 1 and type 2 diabetes mellitus (95), though the risk for type 2 diabetes mellitus was found to be reduced with rare protein-truncating variants of the gene (96). The first prospective cohort study to examine the risk of type 2 diabetes in relation to zinc intakes — the Nurses' Health Study (NHS) — followed 82,297 US registered female nurses for 24 years. The data analysis showed an 8% lower risk of type 2 diabetes with the highest versus lowest intake of dietary zinc (median values, 11.8 mg/day versus 4.9 mg/day) (97). This finding was consistent with the result of the Australian Longitudinal Study on Women's Health (ALSWH) that enrolled 8,921 women for six years and showed a 50% lower risk of diabetes with the highest versus lowest intake of energy-adjusted dietary zinc (98). Both NHS and ALSWH studies also reported a reduced risk of diabetes with higher versus lower zinc-to-heme iron ratios in the diet (97, 98), although the significance is unclear as nonheme iron, rather than heme iron, is known to interfere with dietary zinc absorption (see Nutrient interactions). Heme iron may be an indicator of red meat consumption, which has been positively associated with the risk of type 2 diabetes (99). However, two other prospective cohort studies — the Multi-Ethnic Study of Atherosclerosis (MESA; 4,982 participants) and the National Institutes of Health-American Association of Retired Persons (NIH-AARP) Diet and Health Study (232,007 participants) — failed to find evidence for an association between zinc intake and risk of type 2 diabetes (100, 101). Another recent prospective cohort study, the Malmo Diet and Cancer Study in 26,132 middle-aged Swedish participants followed for 19 years, found an increased risk of diabetes with higher dietary zinc intakes yet a lower risk of diabetes in zinc supplement users (versus non-users) and in those with a higher zinc-to-iron intake ratio (102). The authors reported a stronger inverse association between zinc-to-iron intake ratio and risk of diabetes among obese participants carrying a specific *SLC30A8* genotype (102).

The results of a few short-term intervention studies suggest that zinc supplementation may improve glucose handling in subjects with prediabetes. A 2015 systematic review identified three short trials (4 to 12 weeks) conducted in adults with prediabetes and found little evidence of an improvement in insulin resistance with zinc supplementation (103). However, a 2016 randomized, placebo-controlled trial in 55 Bangladeshi with prediabetes showed that daily supplementation with zinc sulfate (30 mg/day for 6 months) improved fasting blood glucose, as well as measures of β-cell function and insulin sensitivity (104). Similar observations were made in another recent trial in 100 Sri Lankan randomized to receive daily supplementation with zinc (20 mg of elemental zinc) or a placebo for one year (105). Supplemental zinc improved zinc status and measures of glycemic control (105). Large-scale, long-term studies are necessary to provide definite conclusions regarding the potential benefit of zinc supplementation in subjects at risk of type 2 diabetes.

Disease Treatment

Doses of supplemental zinc in many of the below-mentioned clinical trials exceeded the tolerable upper intake level (UL). Such high intake of supplemental zinc may lead to adverse health effects with prolonged use (see Safety).

Wilson's disease

The protein, ATP7B, is responsible for the excretion of hepatic copper into the biliary tract, and its impairment in Wilson's disease results in an increased concentration of 'free' copper (i.e., not bound to the copper-carrying protein, ceruloplasmin) in blood, an increased excretion of copper in the urine (hypercupriuria), the deposition of copper in part of the cornea (forming Kayser-Fleischer rings), and the accumulation of copper in the liver and brain (106). This inherited condition is progressive and fatal if untreated. The standard-of-care for symptomatic patients usually includes an initial phase (around 2-6 months) of copper chelation with agents, such as penicillamine or trientine (triethylenetetramine), followed by lifelong maintenance therapy with penicillamine and/or trientine and/or zinc salts (107). Patients presenting without symptoms can be treated with maintenance therapeutic doses of a chelating agent or with zinc (108). Zinc-induced metallothionein in the intestinal mucosa binds copper and prevents its absorption (see Nutrient interactions). There is growing evidence to suggest that zinc salts are a safer, much cheaper, and efficacious alternative to metal-chelating agents — which have been associated with a worsening of symptoms during the initial phase of treatment in some patients (109). The use of zinc is advocated as safe and efficacious in both pediatric (110, 111) and adult patients (112-114).

Common cold

Zinc lozenges

There is no proven treatment for common cold (115). The use of zinc lozenges within 24 hours of the onset of cold symptoms, and continued intake every two to three hours while awake until symptoms resolve, have been advocated for reducing the duration of the common cold (116). Several clinical trials examining the effect of zinc have been published to date. A 2012 systematic review and meta-analysis of 13 randomized controlled trials reported that zinc supplementation in the form of lozenges or syrup shortened the duration of cold symptoms, but there was significant heterogeneity (inconsistent effects across the included studies) for the primary outcomes (117). A 2013 Cochrane review confirmed that oral zinc administrated within 24 hours of symptom onset could reduce the duration of cold symptoms (14 trials, 1,656 participants) (118). Subgroup analyses also suggested that oral zinc was effective regardless of the age of participants (children or adults) and the type of zinc formulation (gluconate/acetate lozenges or sulfate syrup). In addition, beneficial effects on cold duration were seen in trials that provided more than 75 mg/day of zinc but not in trials that used lower doses. The pooled analysis of five trials found no evidence of an effect of oral zinc on the severity of cold symptoms. The analysis of secondary trial outcomes suggested a faster resolution of specific cold symptoms (cough, nasal congestion, nasal drainage, sore throat) and a lower proportion of participants exhibiting cold symptoms after seven days of treatment in zinc- versus placebo-supplemented participants (118).

Inconsistent findings among trials have been partly attributed to different amounts of zinc released from various forms used in the lozenges (particularly zinc acetate and zinc gluconate) (119, 120). It has been argued that the unpleasant taste of zinc gluconate forming complexes with carbohydrates may have led to poor compliance, thereby explaining negative trial results (119, 121). However, when a meta-analysis was recently conducted on results from seven trials (575 participants) that employed zinc lozenges at doses >75 mg/day, there was no evidence of a difference in efficacy observed between trials that used either zinc acetate (3 trials) or zinc gluconate (4 trials) (122).

With numerous well-controlled trials and meta-analyses, the efficacy of zinc lozenges or syrup in treating common cold symptoms is no longer questionable. A meta-analysis of seven trials recently reported a 33% reduction in the duration of cold symptoms with the intake of zinc lozenges (>75 mg/day of elemental zinc) (122). However, many supplemental zinc formulations available over-the-counter have been found to release zero zinc ions (i.e., the biologically active form of zinc) or to contain additives (e.g., magnesium, certain amino acids, citric acid) that either cancel out the benefit of zinc or worsen cold symptoms (119).

Finally, although taking zinc lozenges for a cold every two to three hours while awake will result in daily zinc intakes well above the tolerable upper intake level (UL) of 40 mg/day for adults (see Safety), the use of zinc at daily doses of 50 to 180 mg for one to two weeks has not resulted in serious side effects (117). Bad taste and nausea were the most frequent adverse effects reported in therapeutic trials (117). Use of zinc lozenges for prolonged periods (e.g., 6-8 weeks) is likely to result in copper deficiency (see Nutrient interactions and Safety).

Intranasal zinc (zinc nasal gels and nasal sprays)

Intranasal zinc preparations, designed to be applied directly to the nasal epithelium (cells lining the nasal passages), are marketed as over-the-counter cold remedies. While two placebo-controlled trials found that intranasal zinc gluconate modestly shortened the duration of cold symptoms (123, 124), another one found intranasal zinc to be of no benefit (125). The pooled analysis of these three trials showed no overall benefit of intranasal zinc on the risk of still experiencing cold symptoms by day 3 (126). The existence of a mouth-nose biologically close electric circuit (BCEC) has been proposed to explain the efficacy of oral rather than intranasal zinc delivery (119). Specifically, it is suggested that the positively charged interior of the nose repels ionic zinc (Zn^{2+}) such that ionic zinc delivered by throat lozenges and migrating from the mouth to the nose are more effective against rhinovirus infection than those directly delivered into the nose (119). Of serious concern are several case reports of individuals experiencing loss of the sense of smell (anosmia) after using intranasal zinc as a cold remedy (127). Since zinc-associated anosmia may be irreversible, intranasal zinc preparations should be avoided.

Age-related macular degeneration

Age-related macular degeneration (AMD) is a degenerative disease of the macula and a leading cause of blindness in people aged >65 years in the US (128). The macula is the portion of the retina in the back of the eye involved with central vision. Zinc is hypothesized to play a role in the development of AMD for several reasons: (1) zinc is found at high concentrations in the part of the retina affected by AMD, (2) retinal zinc content has been shown to decline with age, and (3) the activities of some zinc-dependent retinal enzymes have been shown to decline with age. To date, prospective cohort studies have shown limited evidence suggesting an association between dietary zinc intake and the incidence of AMD (129-131).

However, an early randomized controlled trial provoked interest when it found that 200 mg/day of zinc sulfate (81 mg/day of elemental zinc) over two years limited the loss of vision in patients with AMD (132). Yet a later trial using the same dose and duration found no benefit to patients with a more advanced form of AMD in one eye (133). Small trials have generally not reported a protective effect of vitamin and mineral supplementation on AMD (134, 135). However, a randomized, double-blind, placebo-controlled trial in 74 patients with AMD reported that supplementation with 50 mg/day of zinc monocysteine for six months improved measures of macular function, including visual acuity, contrast sensitivity, and photorecovery (136). A large randomized, placebo-controlled trial of daily supplementation with antioxidants (500 mg of vitamin C, 400 IU of vitamin E, and 15 mg of β-carotene) and high-dose zinc (80 mg of zinc as zinc oxide and 2 mg of copper as cupric oxide) — the Age-Related Eye Disease Study (AREDS) — found that administration of high-dose zinc alone or with the antioxidant combination to individuals with signs of moderate-to-severe macular degeneration significantly reduced the risk of developing advanced macular degeneration over a mean follow-up of 6.3 years (137). A follow-up analysis conducted four years after the cessation of the trial in 2001, including nearly 85% of the surviving participants, found that the benefit of the AREDS (combined antioxidants plus zinc) formulation had persisted (138). Indeed, the odds of developing late AMD, especially neovascular AMD, was lower in both participants with a low risk of developing AMD and those who were at risk and recommended to continue taking the AREDS formulation after the trial ended. There was, however, no effect of AREDS formulation on the risk of developing central geographic atrophy (138). Another trial, AREDS2, examined the effect of an AREDS formulation without β-carotene and/or containing 25 mg instead of 80 mg of zinc (139). The trial showed no apparent difference in the risk of developing advanced AMD with the use of AREDS formulations containing either 25 mg or 80 mg of zinc and/or β-carotene (140). A recent meta-analysis of five trials (including the original AREDS study) confirmed the protective effect of supplemental zinc against neovascular and advanced AMD (141).

In conclusion, the AREDS formulation combining antioxidants and zinc (25 mg or 80 mg) may delay the progression of the disease in patients with AMD. Patients, especially smokers and those with vascular disease, are advised to discuss with their physician the benefits versus potential harms that could be associated with the long-term use of high-dose antioxidant vitamins and carotenoids (141).

Diabetes mellitus

Type 2 diabetes mellitus

Poor glycemic control and frequent urination in patients with diabetes mellitus may be driving urinary loss of zinc and contribute to marginal zinc deficiency (142, 143). Yet, because of the role of zinc in β-cell function and insulin action (see Disease Prevention), a number of randomized controlled trials have examined whether supplementation with zinc (alone or with other minerals and vitamins) could play a role in diabetes management, especially by improving glycemic control in people with type 2 diabetes (15). Out of the 12 trials that measured participants' zinc status at baseline, supplementation with zinc (20-240 mg/day) for 4 to 16 weeks improved fasting blood glucose in patients who presented with zinc deficiency (6 studies). Supplemental zinc also reduced the proportion of glycated hemoglobin (HbA1c) in two trials conducted in zinc-deficient participants, yet not in four studies including participants without zinc deficiency (15). Patients with type 2 diabetes should ensure that their diet provides enough zinc to cover their needs, especially if their blood glucose is poorly controlled.

Gestational diabetes mellitus

Gestational diabetes mellitus is defined as hyperglycemia that is first diagnosed during pregnancy. The condition is associated with an increased risk for adverse pregnancy outcomes (144). A group of investigators in Iran conducted two small randomized, placebo-controlled trials to examine the effect of zinc supplementation in pregnant women with gestational diabetes. Supplemental zinc (30 mg/day) for six weeks during pregnancy improved zinc status, reduced fasting blood glucose, and improved insulin sensitivity in women with gestational diabetes but had no impact on pregnancy outcomes, including the need for cesarean section, need for insulin therapy, newborn's birth size and Apgar scores, or incidence of hyperbilirubinemia (145, 146). Similar improvements of markers of glycemic control were reported in another placebo-controlled trial that randomized pregnant women with gestational diabetes to receive zinc (4 mg) together with magnesium (100 mg), calcium (400 mg), and vitamin D (200 IU) twice a day for six weeks (147). There was also some evidence suggesting that supplemental zinc might help correct other metabolic disorders (e.g., abnormal blood lipid profile) associated with gestational diabetes (147, 148).

HIV/AIDS

Sufficient zinc is essential to maintain immune system function, and HIV-infected individuals are particularly susceptible to zinc deficiency. In HIV-infected patients, low serum zinc concentrations have been associated with disease progression and increased mortality (149, 150). In one study conducted in AIDS patients, 45 mg/day of zinc for one month resulted in a decreased incidence of opportunistic infections compared to placebo (151). A placebo-controlled trial in 231 HIV-positive adults with low zinc status found that zinc supplementation (12 mg/day for women and 15 mg/day for men) for 18 months reduced the incidence of immunological failure (defined by a $CD4^+$ count <200 cells/mm^3) by 76% and the rate of diarrhea by 60% (152). A 2011 systematic review that identified three randomized controlled trials in primarily resource-poor settings concluded that zinc supplementation was safe and efficacious in reducing opportunistic infections in HIV-positive adults (153).

Evidence of benefits of zinc supplementation in HIV-positive pregnant women and children is very limited. In a double-blind, randomized, placebo-controlled trial in Tanzania, the administration of zinc (25 mg/day) to women between 12 and 27 weeks' gestation until six months after delivery failed to reduce maternal viral load or limit mother-to-child HIV transmission (154). A randomized placebo-controlled trial of zinc supplementation (10 mg/day for 6 months) in 96 HIV-positive children (6 months to 5 years old) in South Africa showed no effect on $CD4^+$ count and viral load (155). There was evidence showing a reduction in the incidence of watery diarrhea in zinc-supplemented children compared to those taking a placebo, yet no differences in the incidence of pneumonia, ear infection, or upper respiratory tract infection (155). Another trial in Uganda showed that supplemental zinc in children with severe pneumonia effectively reduced case fatality regardless of children's HIV status (156). While zinc supplementation during pregnancy and infancy is recommended in populations likely to be zinc deficient (43, 71, 75), its use in HIV infection management requires further investigation (157).

Alzheimer's disease

Abnormal homeostasis of trace metals, in particular copper and zinc, has been reported in individuals affected by Alzheimer's disease — the most common form of dementia. Specifically, results from case-control studies have shown higher serum copper concentrations and lower serum zinc concentrations in people with Alzheimer's disease compared to cognitively healthy controls (158-160). Based on the utilization of zinc salts in Wilson's disease, it has been proposed that zinc supplementation could improve zinc and copper status and limit further cognitive deterioration in individuals with Alzheimer's disease. The use of slow-release zinc acetate (150 mg/day for six months) in a randomized, placebo-controlled study of 60 patients with mild-to-moderate Alzheimer's disease corrected low zinc status and decreased serum 'free' copper (i.e., unbound to ceruloplasmin) (161). Moreover, when a post-hoc analysis was restricted to participants over 70 years of age (N=29), it was found that zinc supplementation prevented the deterioration of cognition scores over the trial period (161). Additional evidence is needed to confirm whether zinc supplementation could play a role in stabilizing cognitive deficits in older adults with dementia.

Depression

A data analysis of the Boston Area Community Health (BACH) survey, including 3,708 participants (ages, 30-79 years), reported higher odds of depression symptoms in women (but not in men) in the lowest versus highest quartiles of total (median values, 8.7 mg/day versus 26.8 mg/day) and dietary (median values, 7.6 mg/day versus 13.1 mg/day) zinc intakes (162). The possibility that zinc could play a role in preventing or alleviating depression has been explored in two trials conducted by one research group. The data from these trials were analyzed following a per-protocol approach (i.e., restricted to the participants who completed the studies). A preliminary randomized, double-blind, placebo-controlled trial in 20 subjects (mean age, 43 years) treated for major depression showed that supplementation with 25 mg/day of zinc reduced depression symptoms at 6 and 12 weeks as assessed by the Hamilton Depression Rating Scale (HDRS) and Beck Depression Inventory (BDI) scores (163). A second placebo-controlled trial in 60 participants treated with the antidepressant imipramine (Tofranil; 100-200 mg/day) assessed the therapeutic response to supplemental zinc (25 mg/day) using HDRS, BDI, Clinical Global Impression scale (CGI), and Montgomery-Åsberg Depression Rating Scale (MADRS) scores (164). Zinc supplementation improved score-based measures of therapeutic response and remission after six weeks but only when the analysis was restricted to participants resistant to imipramine. There was, however, no evidence of an effect of zinc after 12 weeks (164).

Neonatal sepsis

Sepsis is a life-threatening condition that causes organ dysfunction as a consequence of a dysregulated host's response to infection (165). Sepsis is accompanied by changes in zinc homeostasis characterized in particular by a decrease in serum zinc concentration and an increase in liver zinc concentration (166). These changes in zinc distribution are thought to be part of a host's defense mechanism whereby the host can limit zinc availability to pathogens, as well as stimulate the immune system. Such a mechanism has been described for other transition metals, including iron and manganese (167). However, lower serum zinc concentrations in critically ill patients at high risk of organ failure have been associated with recurrent sepsis episodes and poorer outcomes (168, 169). A 2018 systematic review identified four trials that examined the effect of zinc supplementation in newborns with sepsis (166). Zinc supplementation was found to result in decreased inflammation (170) and better neurological development (171, 172). Three out of four trials that examined the rate of mortality showed no effect of zinc supplementation (170, 172, 173).

Sources

Food sources

Shellfish, beef, and other red meats are rich sources of zinc; nuts and legumes are relatively good plant sources of zinc. Zinc bioavailability (the fraction of zinc retained and used by the body) is relatively high in meat, eggs, and seafood because of the relative absence of compounds that inhibit zinc absorption and the presence of sulfur-containing amino acids (cysteine and methionine) that improve zinc absorption. Zinc in whole-grain products and plant proteins is less bioavailable due to their relatively high content of phytate, which inhibits zinc absorption (174). The enzymatic action of yeast reduces the level of phytate in foods; therefore, leavened whole-grain breads have more bioavailable zinc than unleavened whole-grain breads.

National dietary surveys in the US estimate that average dietary zinc intake from naturally and fortified food is about 12.3 mg/day in adults, with about 12% of the adult population being at risk for inadequate intake (175). The zinc content of some foods relatively rich in zinc is listed in **Table 2** in milligrams (mg). For more information on the nutrient content of specific foods, search USDA's FoodData Central (176).

Table 2. Some Food Sources of Zinc

Food	Serving	Zinc (mg)
Oyster, cooked	6 medium	27-50
Beef, chuck, blade roast, cooked	3 ounces*	8.7
Beef, ground, 90% lean meat, cooked	3 ounces	5.4
Crab, Dungeness, cooked	3 ounces	4.7
Fortified, whole-grain toasted oat cereal	1 cup	3.8
Turkey, dark meat, cooked	3 ounces	3.0
Pork, loin, blade roast, cooked	3 ounces	2.7
Soybeans, dry roasted	½ cup	2.2
Chicken, roasting, dark meat, cooked	3 ounces	1.8
Pine nuts	1 ounce	1.8
Cashews	1 ounce	1.6
Yogurt, plain, low fat	6 ounces	1.5
Sunflower seed kernels	1 ounce	1.5
Pecans	1 ounce	1.3
Brazil nuts	1 ounce	1.2
Chickpeas (garbanzo beans), cooked	½ cup	1.2
Milk	1 cup (8 fl. oz.)	1.1
Cheese, cheddar	1 ounce	1.0
Almonds	1 ounce	0.9
Beans, baked	½ cup	0.9
*A three-ounce serving of meat is about the size of a deck of cards.		

Supplements

A number of zinc supplements are commercially available, including zinc acetate, zinc gluconate, zinc picolinate, and zinc sulfate. Zinc picolinate has been promoted as a more absorbable form of zinc, but few data support this idea in humans. Limited work in animals suggests that increased intestinal absorption of zinc picolinate may be offset by increased elimination (29).

Safety

Toxicity

Acute toxicity

Isolated outbreaks of acute zinc toxicity have occurred as a result of the consumption of food or beverages contaminated with zinc released from galvanized containers. Signs of acute zinc toxicity are abdominal pain, diarrhea, nausea, and vomiting. Single doses of 225 to 450 mg of zinc usually induce vomiting. Milder gastrointestinal distress has been reported at doses of 50 to 150 mg/day of supplemental zinc. Metal fume fever has been reported after the inhalation of zinc oxide fumes. Specifically, profuse sweating, weakness, and rapid breathing may develop within eight hours of zinc oxide inhalation and persist for 12 to 24 hours after exposure is terminated (6, 29).

Adverse effects

The major consequence of long-term consumption of excessive zinc is copper deficiency. Total zinc intakes of 60 mg/day (50 mg supplemental and 10 mg dietary zinc) for up to 10 weeks have been found to result in signs of copper deficiency (29). Copper deficiency has also been reported following chronic use of excessive amounts of zinc-containing denture creams (≥2 tubes per week containing 17-34 mg/g of zinc) (177). In order to prevent copper deficiency, the US Food and Nutrition Board set the tolerable upper intake level (UL) for adults at 40 mg/day, including dietary and supplemental zinc (**Table 3**) (29).

Table 3. Tolerable Upper Intake Level (UL) for Zinc

Age Group	UL (mg/day)
Infants 0-6 months	4
Infants 7-12 months	5
Children 1-3 years	7
Children 4-8 years	12
Children 9-13 years	23
Adolescents 14-18 years	34
Adults 19 years and older	40

Intranasal zinc

Intranasal zinc is known to cause a loss of the sense of smell (anosmia) in laboratory animals (178), and there have been several case reports of individuals who developed anosmia after using intranasal zinc gluconate (127). Since zinc-associated anosmia may be irreversible, the use of zinc nasal gels and sprays should be avoided.

Drug interactions

The use of zinc supplements decreases the absorption of certain medications, including cephalexin (Keplex) and penicillamine (Cuprimine, Depen), as well as the antiretroviral drugs atazanavir (Reyataz) and ritonavir (Norvir) (179). Concomitant administration of zinc supplements with certain medications like tetracycline and quinolone antibiotics may decrease the absorption of both zinc and the medications, potentially reducing drug efficacy. Taking zinc supplements and these medications at least two hours apart should prevent this interaction.

The therapeutic use of metal-chelating agents, such as penicillamine (used to treat copper overload in Wilson's disease) and diethylenetriamine pentaacetate (DTPA; used to treat iron overload), has resulted in severe zinc deficiency. Anticonvulsant drugs, especially sodium valproate, may also precipitate zinc deficiency. Prolonged use of diuretics may increase urinary zinc excretion, resulting in increased loss of zinc. Because supplemental zinc can lower blood glucose, those taking anti-diabetic agents are advised to use zinc supplements with caution.

Linus Pauling Institute Recommendation

The RDA for zinc (8 mg/day for adult women and 11 mg/day for adult men) appears sufficient to prevent deficiency in most individuals, but the lack of sensitive indicators of zinc nutritional status in humans makes it difficult to determine the level of zinc intake most likely to promote optimum health. Following the Linus Pauling Institute recommendation to take a multivitamin/mineral supplement will generally provide at least the RDA for zinc. Daily total (supplemental + dietary) intakes of zinc should not exceed the UL (40 mg/day for adults) in order to limit the risk of copper deficiency in particular (see Safety).

Older adults (>50 years)

Although the requirement for zinc is not known to be higher for older adults, many have inadequate dietary zinc intakes (180, 181). A reduced capacity to absorb zinc, increased likelihood of disease states that alter zinc utilization, and increased use of drugs that decrease zinc bioavailability may all contribute to an increased risk of mild zinc deficiency in older adults. Adequate dietary intake of zinc is essential for older adults because the consequences of mild zinc deficiency, such as impaired immune system function, are especially relevant to maintenance of their health.

Summary

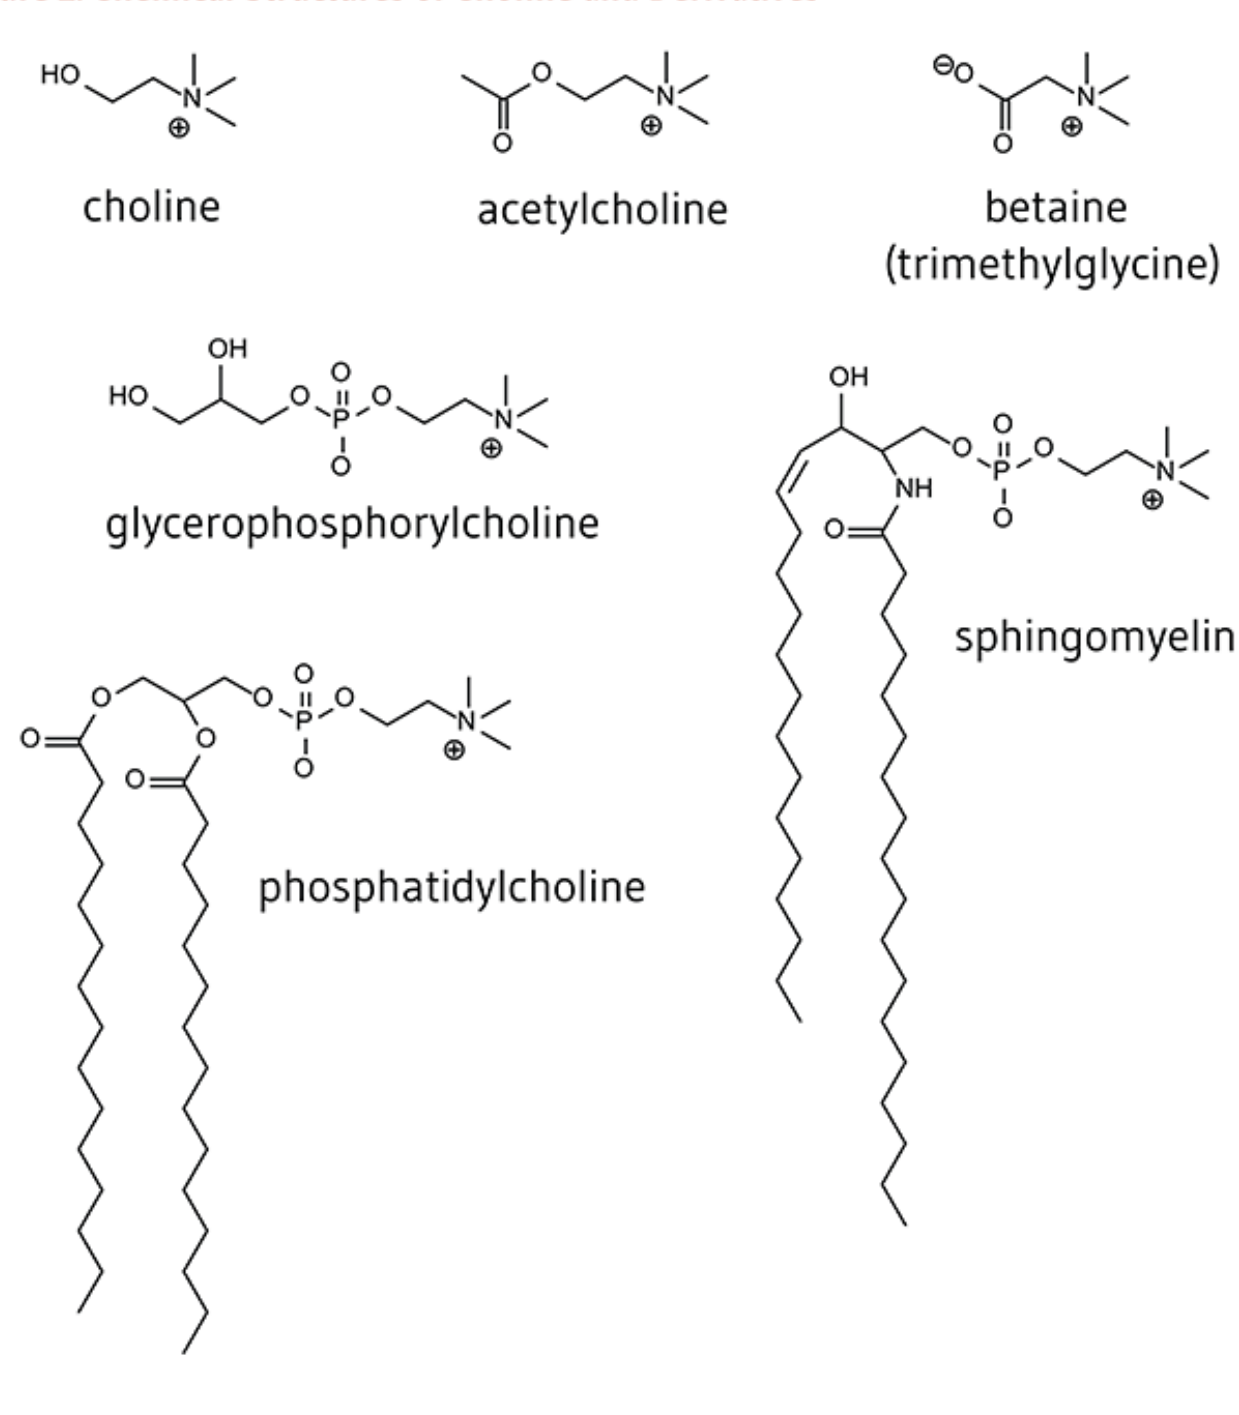
- Choline is a vitamin-like essential nutrient and a methyl donor involved in many physiological processes, including normal metabolism and transport of lipids, methylation reactions, and neurotransmitter synthesis. *(More information)*
- Choline deficiency causes muscle damage and abnormal deposition of fat in the liver, which results in a condition called nonalcoholic fatty liver disease. Genetic predispositions and gender can influence individual variation in choline requirements and thus the susceptibility to choline deficiency-induced fatty liver disease. *(More information)*
- The recommended adequate intake (AI) of choline is set at 425 milligrams (mg)/day for women and 550 mg/day for men. *(More information)*
- Choline is involved in the regulation of homocysteine concentration in the blood through its metabolite betaine. There is currently no convincing evidence that high choline intakes could benefit cardiovascular health through lowering blood homocysteine. Besides, elevated blood concentrations of trimethylamine N-oxide (TMAO), generated from choline, may increase the risk of cardiovascular events. *(More information)*
- The need for choline is probably increased during pregnancy. Case-control studies examining the relationship between maternal choline status and risk of neural tube defects (NTDs) have given inconsistent results. It is not yet known whether periconceptual choline supplementation could confer protection against NTDs. *(More information)*
- Animal studies have shown that choline is essential for optimal brain development and influences cognitive function in later life. However, in humans, there is not enough evidence to assert that choline supplementation during pregnancy improves offspring's cognitive performance or that it helps prevent cognitive decline in older people. *(More information)*
- Recent intervention studies have found that supplementation with citicoline (a choline derivative) may be useful to limit neurologic damage in stroke patients and improve retinal function in some glaucoma patients. It remains unclear whether citicoline could be used in the treatment of dementias and in head trauma patients. *(More information)*
- *De novo* choline synthesis in humans is not sufficient to meet their metabolic needs. Good dietary sources of choline include eggs, meat, poultry, fish, cruciferous vegetables, peanuts, and dairy products. *(More information)*
- Excessive consumption of choline (≥7,500 mg) has been associated with blood pressure lowering, sweating, fishy body odor, and gastrointestinal side effects. The tolerable upper intake level (UL) for adults is 3,500 mg/day. *(More information)*

Although choline is not by strict definition a vitamin, it is an essential nutrient. Despite the fact that humans can synthesize it in small amounts, choline must be consumed in the diet to maintain health. The majority of the body's choline is found in specialized fat molecules known as phospholipids, the most common of which is called phosphatidylcholine (1).

Function

Choline and compounds derived from choline (i.e., metabolites) serve a number of vital biological functions (**Figure 1**) (1).

Figure 1. Chemical Structures of Choline and Derivatives



Structural integrity of cell membranes

Choline is used in the synthesis of certain phospholipids (phosphatidylcholine and sphingomyelin) that are essential structural components of cell membranes. Phosphatidylcholine accounts for about 95% of total choline in tissues (2). This phospholipid can be synthesized from dietary choline via the cytidine diphosphocholine (CDP-choline) pathway or through the methylation of another phospholipid, phosphatidylethanolamine (**Figure 2**) (3). Sphingomyelin is a type of sphingosine-containing phospholipid (sphingolipid) that is synthesized by the transfer of a phosphocholine residue from a phosphatidylcholine to a ceramide (**Figure 3**). Sphingomyelin is found in cell membranes and in the fatty sheath that envelops myelinated nerve fibers.

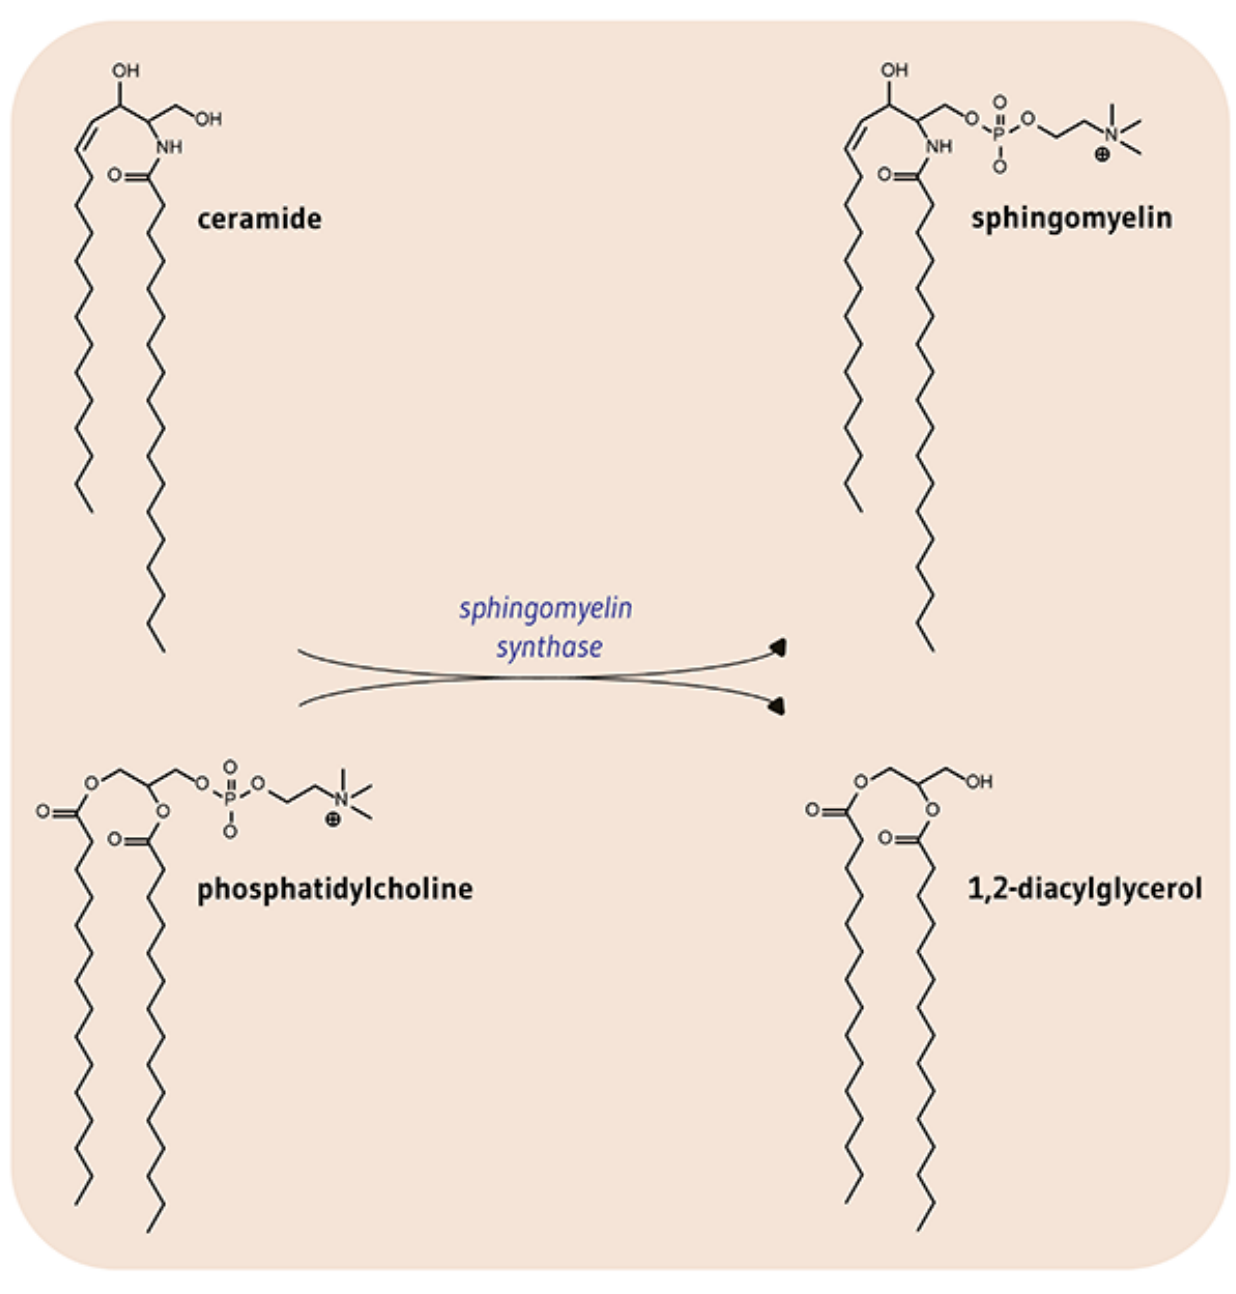
Phosphatidylcholine is synthesized from choline through the methylation of another phospholipid called phosphatidylethanolamine. *AAG, Alkyl-acylglycerol; ADP/ATP, Adenosine di/triphosphate; CMP/CDP/CTP, Cytidine mono/di/triphosphate; DAG, diacylglycerol; PPi, inorganic pyrophosphate; SAH, S-adenosylhomocysteine; SAM, S-adenosylmethionine.*

Figure 3. Synthesis of Sphingomyelin



Sphingomyelin synthase catalyzes the transfer of a phosphocholine headgroup from phosphatidylcholine to ceramide, generating sphingomyelin and 1,2-diacylglycerol.

Cell signaling

The choline-containing phospholipids, phosphatidylcholine and sphingomyelin, are precursors for the intracellular messenger molecules, diacylglycerol and ceramide. Specifically, sphingomyelinases (also known as sphingomyelin phosphodiestarases) catalyze the cleavage of sphingomyelin, generating phosphocholine and ceramide. Diacylglycerol is released by the degradation of phosphatidylcholine by phospholipases. Other choline metabolites known to be cell-signaling molecules include platelet activating factor (PAF) and sphingophosphocholine.

Nerve impulse transmission

Choline is a precursor for acetylcholine, an important neurotransmitter synthesized by cholinergic neurons and involved in muscle control, circadian rhythm, memory, and many other neuronal functions. Choline acetyltransferase catalyzes the acetylation of choline to acetylcholine, and acetylcholine esterase hydrolyzes acetylcholine to choline and acetate (4). CDP-choline administration was also found to stimulate the synthesis and release of a family of neurotransmitters derived from tyrosine (i.e., the catecholamines, including noradrenaline, adrenaline, and dopamine) (5). Of note, non-neuronal cells of various tissues and organ systems also synthesize and release acetylcholine, which then binds and stimulates cholinergic receptors on target cells (reviewed in 6).

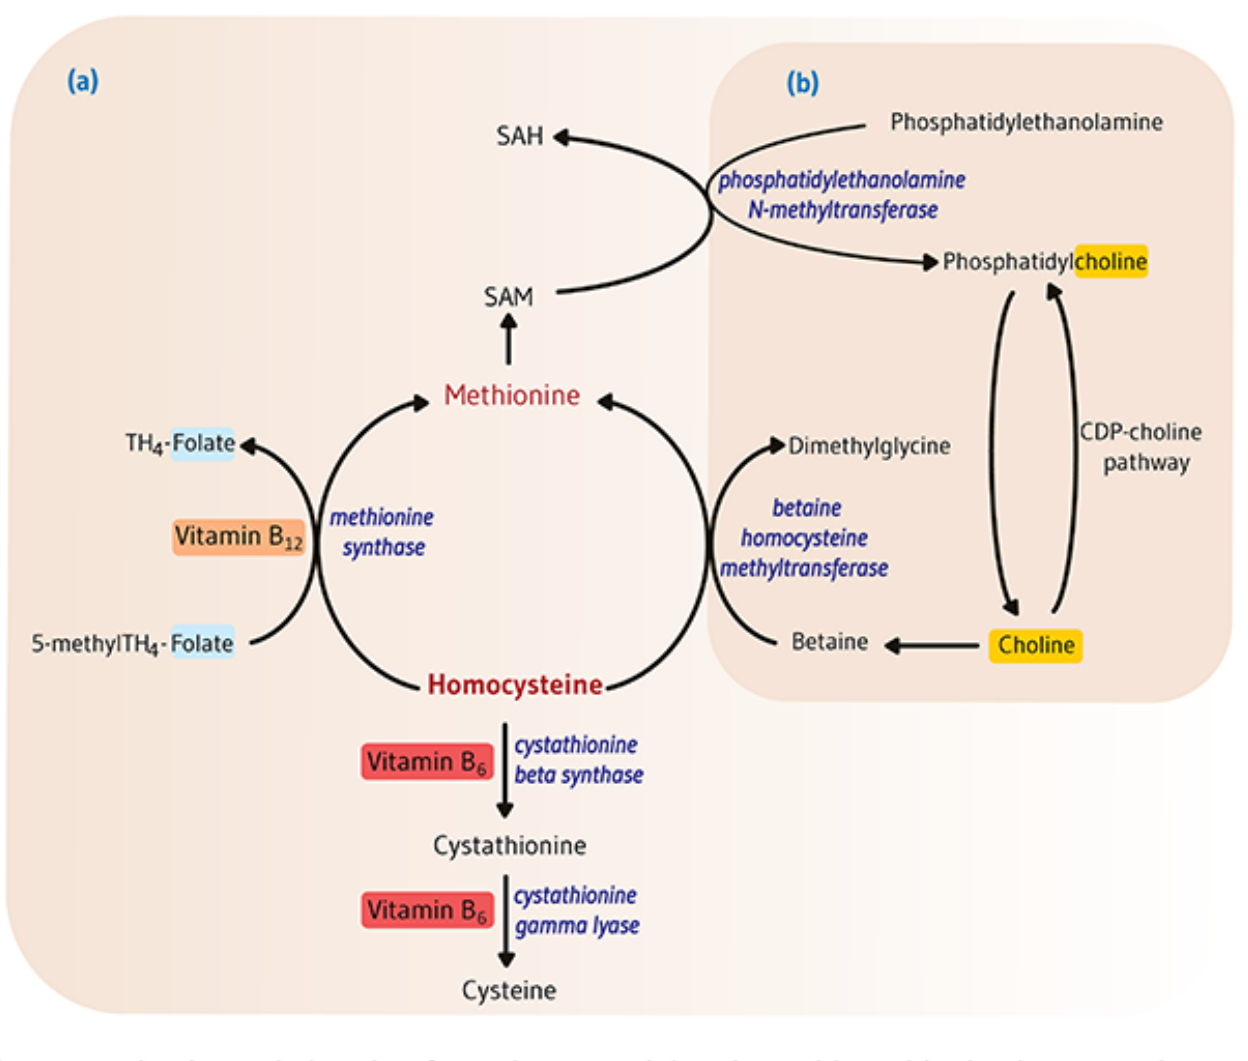
Lipid (fat) transport and metabolism

Fat and cholesterol consumed in the diet are transported to the liver by lipoproteins called chylomicrons. In the liver, fat and cholesterol are packaged into lipoproteins called very-low-density lipoproteins (VLDL) for transport in the bloodstream to extrahepatic tissues. Phosphatidylcholine synthesis by the phosphatidylethanolamine *N*-methyltransferase (PEMT) pathway is required for VLDL assembly and secretion from the liver (7, 8). Without adequate phosphatidylcholine, fat and cholesterol accumulate in the liver (see Deficiency).

Major source of methyl groups

Choline may be oxidized in the liver and kidney to form a metabolite called betaine via a two-step enzymatic reaction. In the mitochondrial inner membrane, flavin adenine dinucleotide (FAD)-dependent choline oxidase catalyzes the conversion of choline to betaine aldehyde, which is then converted to betaine by betaine aldehyde dehydrogenase in either the mitochondrial matrix or the cytosol (2). Betaine is a source of up to 60% of the methyl (CH_3) groups required for the methylation of homocysteine (9). Betaine homocysteine methyltransferase (BHMT) uses betaine as a methyl donor to convert homocysteine to methionine in one-carbon metabolism (**Figure 4**). The ubiquitous vitamin B_{12}-dependent methionine synthase (MS) enzyme also catalyzes the re-methylation of homocysteine, using the folate derivative, 5-methyltetrahydrofolate, as a methyl donor (see Nutrient interactions). Elevated concentrations of homocysteine in the blood have been associated with increased risk of cardiovascular disease (10).

Figure 4. Homocysteine Metabolism



(a) Homocysteine is methylated to form the essential amino acid methionine in two pathways. The reaction of homocysteine remethylation catalyzed by the vitamin B_{12}-dependent methionine synthase captures a methyl group from the folate-dependent one-carbon pool (5-methyltetrahydrofolate). A second pathway requires a choline derivative, betaine (N,N,N-trimethylglycine), as a methyl donor for the methylation of homocysteine catalyzed by betaine homocysteine methyltransferase (BHMT). The catabolic pathway of homocysteine, known as transsulfuration pathway, converts homocysteine to the amino acid cysteine via two vitamin B_6 (PLP)-dependent enzymes: cystathionine β synthase catalyzes the condensation of homocysteine with serine to form cystathionine, and cystathionine is then converted to cysteine, α-ketobutyrate, and ammonia by cystathionine γ lyase.

(b) Methionine is the precursor of universal methyl donor, S-adenosylmethionine (SAM). Three SAM molecules are required for the methylation of phosphatidylethanolamine to phosphatidylcholine by phosphatidylethanolamine N-methyltransferase (PEMT). Choline can be generated from phosphatidylcholine via the action of phospholipases. Conversely, choline can be converted to phosphatidylcholine via the cytidine diphospho (CDP)-choline pathway. *TH_4-Folate, Tetrahydrofolate.*

Osmoregulation

The conversion of choline to betaine is irreversible. Betaine is an osmolyte that regulates cell volume and protect cell integrity against osmotic stress (especially in the kidney). Osmotic stress has been associated with a reduced BHMT expression such that the role of betaine in osmoregulation may be temporarily prioritized over its function as a methyl donor (2).

Deficiency

Symptoms

Men and women fed intravenously (IV) with solutions that contained adequate methionine and folate but lacked choline have been found to develop a condition called nonalcoholic fatty liver disease (NAFLD) and signs of liver damage that resolved when choline was provided (11). The occurrence of NAFLD is usually associated with the co-presentation of metabolic disorders, including obesity, dyslipidemia, insulin resistance, and hypertension, in subjects with metabolic syndrome. NAFLD is estimated to progress to a more severe condition called nonalcoholic steatohepatitis (NASH) in about one-third of NAFLD patients, as well as to increase the risk of cirrhosis and liver cancer (12).

Because phosphatidylcholine is required in the synthesis of very-low-density lipoprotein (VLDL) particles (see Function), choline deficiency results in impaired VLDL secretion and accumulation of fat in the liver (steatosis), ultimately leading to liver damage. Because low-density lipoprotein (LDL) particles are formed from VLDL particles, choline-deficient individuals also show reduced blood concentrations of LDL-cholesterol (13). Abnormally elevated biomarkers of organ dysfunction in the blood, including creatine phosphokinase, aspartate aminotransferase, and alanine aminotransferase, are corrected upon choline repletion. Choline deficiency-induced organ dysfunction has also been associated with increased DNA damage and apoptosis in circulating lymphocytes (14). In the liver, the accumulation of lipids is thought to impair mitochondrial function, thus reducing fatty acid oxidation and increasing the production of reactive oxygen species (ROS) that trigger lipid peroxidation, DNA damage, and apoptosis. Further, oxidative stress is thought to be responsible for prompting inflammatory processes that can lead to the progression of NAFLD to NASH and cirrhosis (end-stage liver disease) (15).

An intervention study in 57 healthy adults who were fed choline-deficient diets under controlled conditions found that 77% of men, 80% of postmenopausal women, and 44% of premenopausal women developed fatty liver, liver damage, and/or muscle damage (16). These signs of organ dysfunction resolved upon choline reintroduction in the diet. Because estrogen stimulates the endogenous synthesis of phosphatidylcholine via the phosphatidylethanolamine N-methyltransferase (PEMT) pathway, premenopausal women may be less likely to develop signs of choline deficiency in response to a low-choline diet compared to postmenopausal women (17, 18). Further, a notable single nucleotide polymorphism (SNP; rs12325817) of the *PEMT* gene, which may affect the expression and/or activity of the PEMT enzyme, is thought to increase the susceptibility to choline deficiency-induced organ dysfunction (17). Additional genetic polymorphisms occurring in choline and one-carbon metabolic pathways may alter the dietary requirement for choline and thus increase the likelihood of developing signs of deficiency when choline intake is inadequate (19-21). The composition of one's intestinal microbiota has been recently identified as another potential predictor of susceptibility to choline deficiency-induced NAFLD (22). Of note, intestinal microbiota-dependent metabolism of dietary phosphatidylcholine might also be involved in the pathogenesis of cardiovascular disease (see Safety) (23, 24).

See Disease Prevention for more information on fatty liver diseases.

Nutrient interactions

Together with several B-vitamins (i.e., folate, vitamin B_{12}, vitamin B_6, and riboflavin), choline is required for the metabolism of nucleic acids and amino acids, and for the generation of the universal methyl group donor, S-adenosylmethionine (SAM) (see **Figure 4** above). SAM is synthesized from the essential amino acid, methionine. Three molecules of SAM are required for the methylation reaction that converts phosphatidylethanolamine into phosphatidylcholine (see **Figure 2** above). Once SAM donates a methyl group it becomes S-adenosylhomocysteine (SAH), which is then metabolized to homocysteine. Homocysteine can be converted back to methionine in a reaction catalyzed by vitamin B_{12}-dependent methionine synthase, which requires 5-methyltetrahydrofolate (5-meTHF) as a methyl donor. Alternately, betaine (a metabolite of choline) is used as the methyl donor for the methylation of homocysteine to methionine by the enzyme, betaine-homocysteine methyltransferase (BHMT) (1). Homocysteine can also be metabolized to cysteine via the vitamin B_6-dependent transsulfuration pathway (see **Figure 4** above).

Thus, the human requirement for choline is especially influenced by the relationship between choline and other methyl group donors such as folate and S-adenosylmethionine. A low intake of folate leads to an increased demand for choline-derived metabolite, betaine. Moreover, the *de novo* synthesis of phosphatidylcholine is not sufficient to maintain adequate choline nutritional status when dietary intakes of folate and choline are low (25). Conversely, the demand for folate is increased when dietary supply for choline is limited (26).

The Adequate Intake (AI)

In 1998, the Food and Nutrition Board (FNB) of the Institute of Medicine established a dietary reference intake (DRI) for choline (27). The FNB felt the existing scientific evidence was insufficient to calculate an RDA for choline, so they set an Adequate Intake (AI; **Table 1**). The main criterion for establishing the AI for choline was the prevention of liver damage. Yet, common polymorphisms in genes involved in choline or folate metabolism alter one's susceptibility to choline deficiency and thus may affect dietary requirements for choline (see Deficiency) (17, 19).

Table 1. Adequate Intake (AI) for Choline

Life Stage	Age	Males (mg/day)	Females (mg/day)
Infants	0-6 months	125	125
Infants	7-12 months	150	150
Children	1-3 years	200	200
Children	4-8 years	250	250
Children	9-13 years	375	375
Adolescents	14-18 years	550	400
Adults	19 years and older	550	425
Pregnancy	all ages	-	450
Breast-feeding	all ages	-	550

Disease Prevention

Cardiovascular disease

Choline and homocysteine

A large body of research indicates that even moderately elevated levels of homocysteine in the blood increase the risk of cardiovascular disease (CVD) (10). The most common cause of a myocardial infarction or a stroke is the rupture of atherosclerotic plaques in arterial walls causing blood clot formation (thrombogenesis). High homocysteine concentrations may promote the development of atherosclerosis (atherogenesis) and thrombogenesis via mechanisms involving oxidative stress and endothelial dysfunction, inflammation, abnormal blood coagulation, and disordered lipid metabolism (reviewed in 28).

Once formed from dietary methionine, homocysteine can be catabolized to cysteine via the transsulfuration pathway or re-methylated to methionine (see **Figure 4** above). Folate and choline are involved in alternate pathways that catalyze the re-methylation of homocysteine (see Nutrient interactions). Specifically, choline is the precursor of betaine, which provides a methyl group for the conversion of homocysteine to methionine via the enzyme, betaine-homocysteine methyltransferase (BHMT). While the amount of homocysteine in the blood is regulated by several nutrients, including folate and choline, conditions that cause damage to the liver like nonalcoholic steatohepatitis (NASH) may also affect homocysteine metabolism (29).

Dietary intakes of choline and betaine and CVD

Because both folate- and choline-dependent metabolic pathways catalyze the re-methylation of homocysteine, dietary intakes of both nutrients need to be considered when the association between homocysteine concentrations and cardiovascular disease is assessed. Yet, despite its relevance, the relationship of betaine and choline to homocysteine metabolism has been only lightly investigated in humans, essentially because the choline content of foods could not be accurately measured until recently. In preliminary intervention studies, pharmacologic doses of betaine (1,500 to 6,000 mg/day) were found to reduce blood homocysteine concentrations in a small number of volunteers with normal-to-mildly elevated homocysteine concentrations (30-33). Yet, in a cross-sectional analysis of a large cohort of 16,165 women (ages, 49-79 years), lower betaine doses in the range of dietary intakes were not found to be correlated with homocysteine concentrations (34). This study also showed that levels of choline intake were inversely associated with homocysteine concentrations in the blood. However, an eight-year follow-up study of the cohort failed to show any difference in cardiovascular risk between women in the upper versus bottom quartile of dietary choline intakes (>329 mg/day vs. ≤266 mg/day) (34). The prospective study of the Atherosclerosis Risk in Communities (ARIC) cohort found that the highest vs. lowest quartile (>486 mg/day vs. <298 mg/day) of total choline intakes from food was not significantly associated with the incidence of coronary artery disease in 14,430 middle-aged participants (35). Also, in a recent analysis of the Health Professionals Follow-up Study (HPFS) that enrolled 44,504 men for a period of 24 years, the risk of peripheral artery disease was positively correlated with homocysteine concentrations but neither with betaine nor choline levels of intake (36).

While further research is indicated, convincing evidence that increased dietary intake of choline or betaine could benefit cardiovascular health through lowering homocysteine concentrations in the blood is presently lacking.

Circulating concentrations of choline and betaine and CVD risk

A 1995 study had found that elevated blood homocysteine concentrations in patients who experienced a vascular occlusion were associated with higher urinary excretion of betaine, rather than with reduced intake of choline or betaine or diminished activity of BHMT (37). In a recent prospective study, high urinary betaine excretion was also associated with increased risk of heart failure in 325 nondiabetic subjects who have been hospitalized for acute coronary syndrome (38). In the same study, both top and bottom quintiles of plasma betaine concentrations were associated with an increased risk of secondary acute myocardial infarction. The findings of another prospective study (the Hordaland Health Study) that followed 7,045 healthy adults (ages, 47-49 years and 71-74 years) suggested that high choline and low betaine plasma concentrations were associated with an unfavorable cardiovascular risk profile (39). Indeed, plasma choline was positively associated with a number of cardiovascular risk factors, such as BMI, percentage body fat, waist circumference, and serum triglycerides, and inversely associated with HDL-cholesterol. On the contrary, plasma betaine was positively correlated to HDL-cholesterol and inversely associated with the above-mentioned risk factors as well as with systolic and diastolic blood pressure. More recent studies now suggest that the blood concentration of trimethylamine N-oxide (TMAO), generated from trimethylamine-containing nutrients like dietary choline, rather than that of choline, might influence the risk of cardiovascular events (see Safety).

It is not yet clear whether concentrations of choline, betaine, and/or TMAO in the blood can predict the risk for cardiovascular disease.

Liver diseases

Fatty liver diseases

While a choline-deficient diet results in organ dysfunction and nonalcoholic fatty liver disease (NAFLD) (see Deficiency; 16), it is not known whether suboptimal dietary choline intakes in healthy subjects may contribute to an increased risk for NAFLD. A cross-sectional analysis of two large prospective studies conducted in China – the Shanghai Women's Health Study and the Shanghai Men's Health Study – including 56,195 people (ages, 40-75 years), was recently conducted to assess the association between dietary choline intakes and self-reported diagnosis of fatty liver disease (40). The highest versus lowest quintile of choline intake (412 mg/day vs. 179 mg/day) was associated with a 28% lower risk of fatty liver disease in normal-weight women, but no association was found in overweight or obese women or in men. Another cross-sectional study of 664 individuals with NAFLD or nonalcoholic steatohepatitis (NASH) also reported that disease severity was inversely correlated with dietary choline intakes in postmenopausal women, but not in premenopausal women, men, or children (41).

Liver cancer

In animal models, dietary choline deficiency has been associated with an increased incidence of spontaneous liver cancer (hepatocellular carcinoma) and increased sensitivity to carcinogenic chemicals (9). A number of mechanisms have been proposed to contribute to the cancer-promoting effects of choline deficiency: (1) enhanced liver cell regeneration and tissue sensitivity to chemical insults; (2) altered expression of numerous genes regulating cell proliferation, differentiation, DNA repair, and apoptosis due to improper DNA methylation; (3) increased likelihood of DNA damage caused by mitochondrial dysfunction-induced oxidative stress; and (4) activated protein kinase C-mediated cell-signaling cascade, eventually leading to an increase in liver cell apoptosis (2). Yet, it is not known whether choline deficiency can increase the susceptibility to cancer in humans (2).

Neural tube defects

It is known that folate is critical for normal embryonic development, and maternal supplementation with folic acid decreases the incidence of neural tube defects (NTDs) (42). NTDs include various malformations, such as lesions of the brain (e.g., anencephaly, encephalocele) or lesions of the spine (spina bifida), which are devastating and usually incompatible with life (43). These defects occur between the 21st and 28th days after conception, a time when many women do not realize that they are pregnant (44). While the protective effect of folate against NTD is well established, only a few studies have investigated the role of other methyl group donors, including choline and betaine, in the occurrence of NTDs. A case-control study (424 NTD cases and 440 controls) found that women in the highest versus lowest quartile of periconceptual choline intake (>498.46 mg/day vs. ≤290.41 mg/day) had a 51% lower risk of an NTD-affected pregnancy (45). However, more recent studies failed to find an inverse relationship between maternal choline intake and risk of NTDs (46, 47). Another case-control study (80 NTD-affected pregnancy and 409 controls) in US women found that the lowest concentrations of serum choline (<2.49 mmol/L) during mid-pregnancy were associated with a 2.4-fold higher risk of NTDs (48). Finally, a more recent study, including 71 NTD-affected pregnancies, 214 pregnancies with non NTD malformations, 98 normal pregnancies in women with prior NTD-affected pregnancies, and 386 normal pregnancies, found no associations between maternal blood concentrations of choline during pregnancy, choline- and folate-related genetic variants, and risk of NTDs (49). However, it is important to note that circulating choline concentrations do not accurately reflect dietary intake of choline.

More research is needed to determine whether supplemental choline could add to the protective effect currently being achieved by periconceptual folic acid supplementation.

Cognitive health

Neuro-cognitive development

Increased dietary intake of cytidine 5'-diphosphocholine (CDP-choline or citicoline, a precursor of phosphatidylcholine; see **Figure 2** above) very early in life can diminish the severity of memory deficits in aged rats (50). Choline supplementation of the mothers of unborn rats, as well as rat pups during the first month of life, led to improved performance in spatial memory tests months after choline supplementation had been discontinued (51). A review by McCann et al. discusses the experimental evidence from rodent studies regarding the availability of choline during prenatal development and cognitive function in the offspring (52).

Because of the importance of DNA methylation in normal brain development, neuronal functions, and cognitive processes (53), methyl donor nutrients like choline are essential for optimal brain functioning. However, clinical evidence to determine whether findings in rodent studies are applicable to humans is currently limited. Recently, the analysis of the Seychelles Child Development Nutrition Cohort study reported a lack of an association between plasma concentrations of choline and its related metabolites and cognitive abilities in 256 five-year-old children. Only plasma betaine concentrations were found to be positively correlated with preschool language test scores (54). Yet, because circulating concentrations of choline are not directly related to dietary choline intakes, the study could not evaluate whether maternal choline intakes influence children's brain development.

Project Viva is an ongoing prospective study that has examined the relationship between daily intakes of methyl donor nutrients in 1,210 women during pregnancy and child cognition at three and seven years postpartum. Maternal intake of choline during the first and/or second trimester of pregnancy was not correlated with measures of cognitive performance in children at age 3 years (55). Another report of the study indicated that upper vs. lower quartile of maternal choline intakes during the second trimester of pregnancy (median intakes, 392 mg/day vs. 260 mg/day) was significantly associated with higher visual memory scores in children aged 7 years old (56). Recently, a small randomized, double-blind, placebo-controlled trial in 99 pregnant women (ages, 21-41 years old) evaluated the effect of choline supplementation during pregnancy and lactation on infants' cognitive function at ages 10 and 12 months (57). The results indicated that maternal choline supplementation (750 mg/day of choline in the form of phosphatidylcholine) from 18 weeks of gestation to 3 months' postpartum provided no cognitive benefits in children regarding short-term visio-spatial memory, long-term episodic memory, and language and global development.

Cognitive function in older adults

Cognitive function, including the domains of memory, speed, and executive function, decline gradually with increasing age. The rate of cognitive decline is also influenced by modifiable risk factors like dietary habits. Deficiency in B-vitamins and elevated homocysteine concentrations in the blood have been associated with cognitive impairments in the elderly. Yet, a recent meta-analysis of 11 trials indicated that homocysteine lowering using B-vitamin supplementation fails to limit cognitive decline or improve cognitive performance in older adults (58). The cross-sectional data analysis of a subgroup of 1,391 volunteers (ages, 36-83 years) from the large Framingham Heart Study Offspring cohort has indicated that dietary choline intake was positively associated with specific cognitive functions, namely verbal memory and visual memory (59). Another cross-sectional study of 2,195 individuals (ages, 70-74 years) from the Hordaland Health Study examined cognitive abilities and blood concentrations of various determinants of circulating homocysteine, including choline and betaine (60). Unlike betaine, high vs. low plasma concentrations of free choline (>8.36 mcmol/L vs. ≤8.36 mcmol/L) were found to be significantly associated with a greater performance at cognitive tests assessing sensory motor speed, perceptual speed, executive function, and global cognition. However, in an earlier intervention study that enrolled 235 elderly individuals (mean age, 81 years old) with or without mild vitamin B_{12} deficiency, baseline concentrations of betaine – but not choline – were found to be positively correlated to test scores evaluating the cognitive domains of construction, sensory motor speed, and executive function (61).

More research is needed to determine the effect of choline on the developing brain and whether choline intakes above the RDA may be useful in the prevention of memory loss or dementia in humans.

Disease Treatment

Cerebrovascular diseases

Cerebrovascular diseases (including stroke and sub-acute ischemic cerebrovascular disease) are the main cause of cognitive impairments in older people. Results from experimental studies have suggested that pharmacological doses of citicoline (CDP-choline) could enhance the metabolism of glucose and the biosynthesis of phospholipids and neurotransmitters, while limiting the degradation of phospholipids in neuronal membranes in models of ischemia and neurodegenerative diseases (reviewed in 62). Many short-term intervention studies in older individuals with vascular diseases have found that therapeutic doses of citicoline given either orally, by intramuscular injection, or by intravenous infusion, resulted in improvements in neuropsychological functions, including cognitive, emotional, and behavioral functions (reviewed in 5).

A six-month, multicenter observational study enrolled 197 stroke subjects (mean age, 81.5 years) with a progressive decline of their mental health and general confusion and/or stupor who were initially administered citicoline for 5 or 10 days (2,000 mg/day, by intravenous infusion) within a four-month period, and then for 21 days (1,000 mg/day, by intramuscular injection), repeated once after a seven-day washout period (63). Citicoline treatment was found to be associated with higher scores on cognitive and functional evaluation scales when compared to baseline measurements. However, only randomized controlled trials would be able to assess whether citicoline is protective against vascular damage and cognitive impairment in elderly adults with complex geriatric symptoms.

The International Citicoline Trial on acUte Stroke (ICTUS) is a multicenter and double-blind study that assessed the effect of supplementing 2,298 patients with acute ischemic stroke with citicoline (2,000 mg/day) or a placebo for six weeks on several functional and neurologic outcomes and on mortality rate (64). The results showed no difference between treatment groups after a 90-day follow-up period. Only subgroup analyses found significant benefits of citicoline in patients older than 70 years, in those with moderate rather than severe strokes, and in those not treated with recombinant tissue plasminogen activator (rtPA; standard-of-care treatment). An earlier meta-analysis of small randomized, placebo-controlled trials had reported a positive impact of citicoline (1,000 mg/day, administered for 28 days to 12 months) on memory and behavior in subjects with cognitive deficits associated with cerebrovascular disorders (65). The effect of citicoline was also evaluated in a recent multicenter, open-label, controlled trial (IDEALE trial) in Italian elderly adults (ages, 65-94 years) with evidence of vascular lesions on neuroradiology and mild-to-moderate cognitive deficits, as assessed by Mini-Mental State Examination (MMSE; scores ≥21) (66). Three hundred and forty-nine participants received oral citicoline (1,000 mg/day) or no treatment for nine months. MMSE scores in citicoline-treated individuals remained unchanged while they significantly deteriorated in untreated patients such that MMSE scores between groups were found to be significantly different after three and nine months of treatment. No significant effect was reported in measures of functional autonomy, mood, and behavioral disorders. Another recent open-label, randomized, controlled trial evaluated the effect of citicoline (1,000 mg/day for 12 months) in 347 subjects (mean age, 67.2 years) who suffered an acute stroke. The results demonstrated that citicoline significantly limited cognitive impairments in the domains of attention and executive functions and temporal orientation at 6 and 12 months post-stroke in treated compared to untreated patients (67).

Neurodegenerative diseases

Dementia

Neurodegenerative diseases, such as Alzheimer's disease (AD) and Parkinson's disease (PD), are characterized by progressive cognitive decline and dementia. Dysfunctions in neurotransmitter signaling, affecting cholinergic and dopaminergic pathways in particular, have been involved in the occurrence of cognitive impairments. Deficits in acetylcholine and abnormal phospholipid metabolism have been reported in postmortem studies of the brains of AD patients (11). For these reasons, inhibitors of (acetyl) cholinesterase (which catalyzes the breakdown of acetylcholine) and large doses of lecithin (phosphatidylcholine) have been used to treat patients with dementia due to AD in hopes of raising the amount of acetylcholine available in the brain. While cholinesterase inhibitors have shown positive effects on cognitive functions and measures of clinical global state (68), a systematic review of randomized controlled trials did not find lecithin to be more beneficial than placebo in the treatment of patients with cognitive impairment, vascular dementia, AD, or mixed dementia (69). Limited data are available to assess whether citicoline (CDP-choline) might improve cognitive performance in subjects with AD (70). No recent trial has investigated the effect of citicoline in PD patients.

Glaucoma

Optic neuropathies, including glaucoma, are associated with damage of the optic nerve and loss of visual function. In glaucoma, the progressive deterioration of the optic nerve is caused by loss of a specific neuronal population known as retinal ganglion cells (RGC), such that the condition has been classified as a neurodegenerative disease (71). In a small, double-blind, placebo-controlled study, the effect of citicoline was assessed in 24 subjects affected by open-angle glaucoma and treated with β-blockers. Patients were randomized to follow a therapeutic cycle for a total period of eight years: citicoline (1,000 mg/day, by intramuscular injection) or placebo (β-blockers alone) for a two-month period followed by a four-month washout period (72). Electrophysiological examinations were used to assess the extent of visual dysfunctions, including the simultaneous recordings of Pattern ElectroRetinoGrams (PERG) and Visual Evoked Potentials (VEP). Citicoline was found to enhance retinal function and neural conduction along post-retinal visual pathways, such that responses of the visual cortex to stimuli were significantly improved compared to placebo.

In a similar pilot trial, citicoline efficacy was assessed in 26 volunteers (mean age, 65.4 years) affected by another type of optic neuropathy known as non-arteritic anterior ischemic optic neuropathy (NAION). Oral citicoline (1,600 mg/day) was given for 60 days followed by 60 days of washout, and the therapeutic cycle was repeated once. Compared to placebo, citicoline was found to improve retinal function and post-retinal neural conduction, evidenced by PERG and VEP measures (73). Oral citicoline (four cycles of 500 mg/day for four months followed by a two-month washout period) was also found to significantly reduce the rate of visual field loss and the level of intraocular pressure in 41 patients with progressive glaucoma (74). Larger randomized controlled trials are needed to establish whether citicoline supplementation could be included in the medical treatment of glaucoma.

Traumatic brain injury

For decades, pre-clinical and small clinical studies have investigated the effect of citicoline in the management of patients sustaining a traumatic brain injury (TBI). A systematic review of clinical data suggested that citicoline could hasten the resorption of cerebral edema and improve the recovery of consciousness and neurologic disorders in severe TBI cases (classified by Glasgow Coma Scale [GCS] scores of ≤8). Citicoline also appeared to limit memory deficits and the duration and severity of other post-traumatic symptoms (e.g., headache, dizziness, attention disorder) in TBI patients with mild-to-moderate injuries (GCS scores, 9-15) (reviewed in 5). Although citicoline is currently included in TBI therapeutic regimen in 59 countries, only one multicenter, randomized, double-blind, placebo-controlled trial has recently been conducted in the US. The CiticOline Brain Injury Trial (COBRIT) has enrolled 1,213 patients with mild-to-severe TBI and assessed the effect of enteral or oral citicoline (2,000 mg/day, for 90 days) on functional and cognitive outcomes (measured by components of the TBI Clinical Trials Network Care Battery) (75). No significant benefits of citicoline supplementation over placebo were found at 90 days (end of treatment period) and 180 days. A Cochrane review of the effect of citicoline in the treatment of TBI should be available soon (76).

Sources

De novo synthesis (biosynthesis)

Humans can synthesize choline moieties in small amounts by converting phosphatidylethanolamine into phosphatidylcholine (see **Figure 2** above). Three methylation reactions catalyzed by phosphatidylethanolamine N-methyltransferase (PEMT) are required, each using S-adenosylmethionine (SAM) as a methyl group donor. Choline is generated endogenously when the methylation of phosphatidylethanolamine is coupled with the catabolism of newly formed phosphatidylcholine by phospholipases. This is referred to as *de novo* synthesis of choline. The substitution of choline by serine in the synthesis of phosphatidylserine from phosphatidylcholine by phosphatidylserine synthase-1 also releases choline (4). Because phosphatidylcholine metabolism is a source of endogenous choline, the nutrient was not initially classified as essential (1). Yet, *de novo* choline synthesis in humans is not sufficient to meet their metabolic needs such that healthy humans fed choline-deficient diets develop fatty liver, liver damage, and/or muscle damage (see Deficiency).

Food sources

In the US, mean dietary intakes of choline are well below the recommended AI. According to a US national survey, NHANES 2007-2008, mean dietary intakes of choline were approximately 260 mg/day for women and 396 mg/day for men (77). In a 14-year US prospective study, including over 14,000 middle-aged participants, mean daily intakes of choline were 294 mg and 332 mg in women and men, respectively (35). Eggs, liver, and peanuts, are especially rich in choline (27). Major contributors to choline in the American diet are meat, poultry, fish, dairy foods, pasta, rice, and egg-based dishes (77). Spinach, beets, wheat, and shellfish are also good sources of the choline metabolite, betaine (78). Betaine cannot be converted back to choline but can spare some choline requirements for homocysteine remethylation (1). Phosphatidylcholine, which contains about 13% choline by weight, is the main form of choline in dietary products (79). Lecithin extracts, which comprise a mixture of phosphatidylcholine and other phospholipids, are often added during food processing. Lecithins in processed food have been estimated to increase the daily consumption of phosphatidylcholine by about 1.5 mg/kg of body weight for adults (27).

Strict vegetarians, who consume no meat, milk, or eggs, may be at risk for inadequate choline intake. The total choline contents of some choline-containing foods are listed in milligrams (mg) in **Table 2**. For more information on the nutrient content of specific foods, search the USDA food composition website or the USDA documentation on the choline content of common foods.

Table 2. Some Food Sources of Choline

Food	Serving	Total Choline (mg)
Beef liver, pan fried	3 ounces*	356
Wheat germ, toasted	1 cup	202
Egg	1 large	147
Beef, trim cut, cooked	3 ounces	97
Scallop, cooked, steamed	3 ounces	94
Salmon, pink, canned	3 ounces	75
Chicken, breast, cooked, roasted	3 ounces	73
Atlantic cod, cooked	3 ounces	71
Shrimp, canned	3 ounces	69
Brussel sprouts, cooked, boiled	1 cup	63
Broccoli, cooked, boiled	1 cup, chopped	63
Milk, skim	8 fluid ounces	38
Peanut butter, smooth	2 tablespoons	20
Milk chocolate	1.5-ounce bar	20
Peanuts	1 ounce	15
*A three-ounce serving of meat or fish is about the size of a deck of cards.		

Supplements

CDP-choline (citicoline) and choline salts, such as choline chloride and choline bitartrate, are available as supplements. Phosphatidylcholine supplements also provide choline; however, choline comprises only about 13% of the weight of phosphatidylcholine (79). Therefore, a supplement containing 4,230 mg (4.23 grams) of phosphatidylcholine would provide 550 mg of choline. Although the term "lecithin" is synonymous with phosphatidylcholine when used in chemistry, commercial lecithins are usually prepared from soybean, sunflower, and rapeseed, and may contain anywhere from 20%-90% of phosphatidylcholine. Egg yolk lecithin is a more unlikely source of lecithin in dietary supplements. Moreover, the nature of phosphatidylcholine-containing fatty acids depends on whether lecithin is produced from vegetable, animal, or microbial sources. In particular, soybean lecithin is richer in polyunsaturated fatty acids than egg yolk lecithin (80).

Safety

Toxicity

High doses (10,000 to 16,000 mg/day) of choline have been associated with a fishy body odor, vomiting, salivation, and increased sweating. The fishy body odor results from excessive production and excretion of trimethylamine, a metabolite of choline. In the inherited condition, primary trimethylaminuria (also known as "fish odor syndrome"; see the article on Riboflavin), a defective flavin containing monooxygenase 3 (FMO3) enzyme results in impaired oxidation of trimethylamine in the liver. Disease management includes the use of choline-restricted diets in affected individuals (81).

Taking large doses of choline in the form of phosphatidylcholine (lecithin) does not generally result in fishy body odor, because its metabolism results in little trimethylamine. A dose of 7,500 mg/day of choline was found to have a slight blood pressure lowering (hypotensive) effect, which could result in dizziness or fainting. Choline magnesium trisalicylate at doses of 3,000 mg/day has resulted in impaired liver function, generalized itching, and ringing of the ears (tinnitus). However, it is likely that these effects were caused by the salicylate, rather than the choline in the preparation (27).

In 1998, the Food and Nutrition Board (FNB) of the Institute of Medicine established the tolerable upper intake level (UL) for choline at 3,500 mg/day for adults (**Table 3**). This recommendation was based primarily on preventing hypotension (low blood pressure), and secondarily, on preventing the fishy body odor due to increased excretion of trimethylamine. The UL was established for generally healthy people, and the FNB noted that individuals with liver or kidney disease, Parkinson's disease, depression, or inherited trimethylaminuria might be at increased risk of adverse effects when consuming choline at levels near the UL (27).

Table 3. Tolerable Upper Intake Level (UL) for Choline

Age Group	UL (mg/day)
Infants 0-12 months	Not possible to establish*
Children 1-8 years	1,000
Children 9-13 years	2,000
Adolescents 14-18 years	3,000
Adults 19 years and older	3,500
*Source of intake should be food and formula only.	

Do high choline intakes and/or phosphatidylcholine supplements increase the risk for cardiovascular disease?

Oral supplementation with phosphatidylcholine (250 mg of total choline from food plus 250 mg of supplemental phosphatidylcholine) has been found to result in detectable concentrations of trimethylamine and trimethylamine N-oxide (TMAO) in the blood (23). The intestinal microbiota is directly implicated in the generation of trimethylamine from dietary choline, phosphatidylcholine, and carnitine. Trimethylamine is subsequently converted into TMAO by flavin-containing monooxygenases in the liver. The prospective study that followed 4,007 individuals,with or without cardiovascular disease (CVD) for a three-year period found baseline concentrations of circulating TMAO to be positively correlated with incidence of death, nonfatal myocardial infarction, and stroke – described as major adverse cardiac events (MACE) (23). In the same cohort, MACE risk was found to be about 30% higher in individuals in the highest vs. lowest quartile of choline or betaine plasma concentrations (82). However, depending on gut microbiota composition, the risk of having an adverse cardiovascular event may be lower in individuals with low vs. high circulating TMAO even though choline and/or betaine concentrations in the blood are elevated (82).

Elevated TMAO concentrations have been reported in subjects at increased risk of CVD, such as those with diabetes mellitus (83) or end-stage renal disease (chronic kidney failure) (84), and in patients with cardiac insufficiency (chronic heart failure) (85). Yet, in the latter patients, high plasma concentrations of choline, betaine, and TMAO were not associated with a poorer survival rate after five years of follow-up (85). Finally, supplementation with choline, TMAO, or betaine was found to result in the formation of macrophage-derived foam cells in atherosclerosis-prone mice (24). Foam cells are known to contribute to the development of atherosclerotic lesions (i.e., atherogenesis) by accumulating excessive amounts of lipids within the arterial walls and triggering the secretion of pro-inflammatory cytokines.

Further research is needed to understand how the composition of intestinal microbiota influences the metabolic fate of ingested choline. At present, there is no evidence that dietary choline increases the risk of cardiovascular events.

Drug interactions

Methotrexate, a medication used in the treatment of cancer, psoriasis, and rheumatoid arthritis, inhibits the enzyme dihydrofolate reductase and therefore limits the availability of methyl groups donated from folate derivatives. Rats given methotrexate have shown evidence of diminished nutritional status of choline and greater drug adverse reactions due to liver dysfunction (11, 86). Thus, individuals taking methotrexate may have an increased choline requirement. Treatments with a family of lipid-lowering drugs known as fibrates (e.g., fenofibrate, bezofibrate) have been associated with an increased excretion of betaine in the urine and a rise in homocysteine concentration in the blood of patients with diabetes mellitus or metabolic syndrome (87, 88). If the benefits of fibrate therapy are indeed mitigated by fibrate-induced betaine deficiency, the use and safety of supplementing patients with betaine would need to be considered (89).

Linus Pauling Institute Recommendation

Little is known regarding the amount of dietary choline required to promote optimum health or prevent chronic diseases in humans. The Linus Pauling Institute supports the recommendation by the Food and Nutrition Board of 550 mg/day for adult men and 425 mg/day for adult women. A varied diet should provide enough choline for most people, but strict vegetarians who consume no milk or eggs may be at risk of inadequate choline intake.

Older adults (>50 years)

Little is known regarding the amount of dietary choline most likely to promote optimum health or prevent chronic diseases in older adults. At present, there is no evidence to support a different recommended intake of choline from that of younger adults (550 mg/day for men and 425 mg/day for women).

Summary

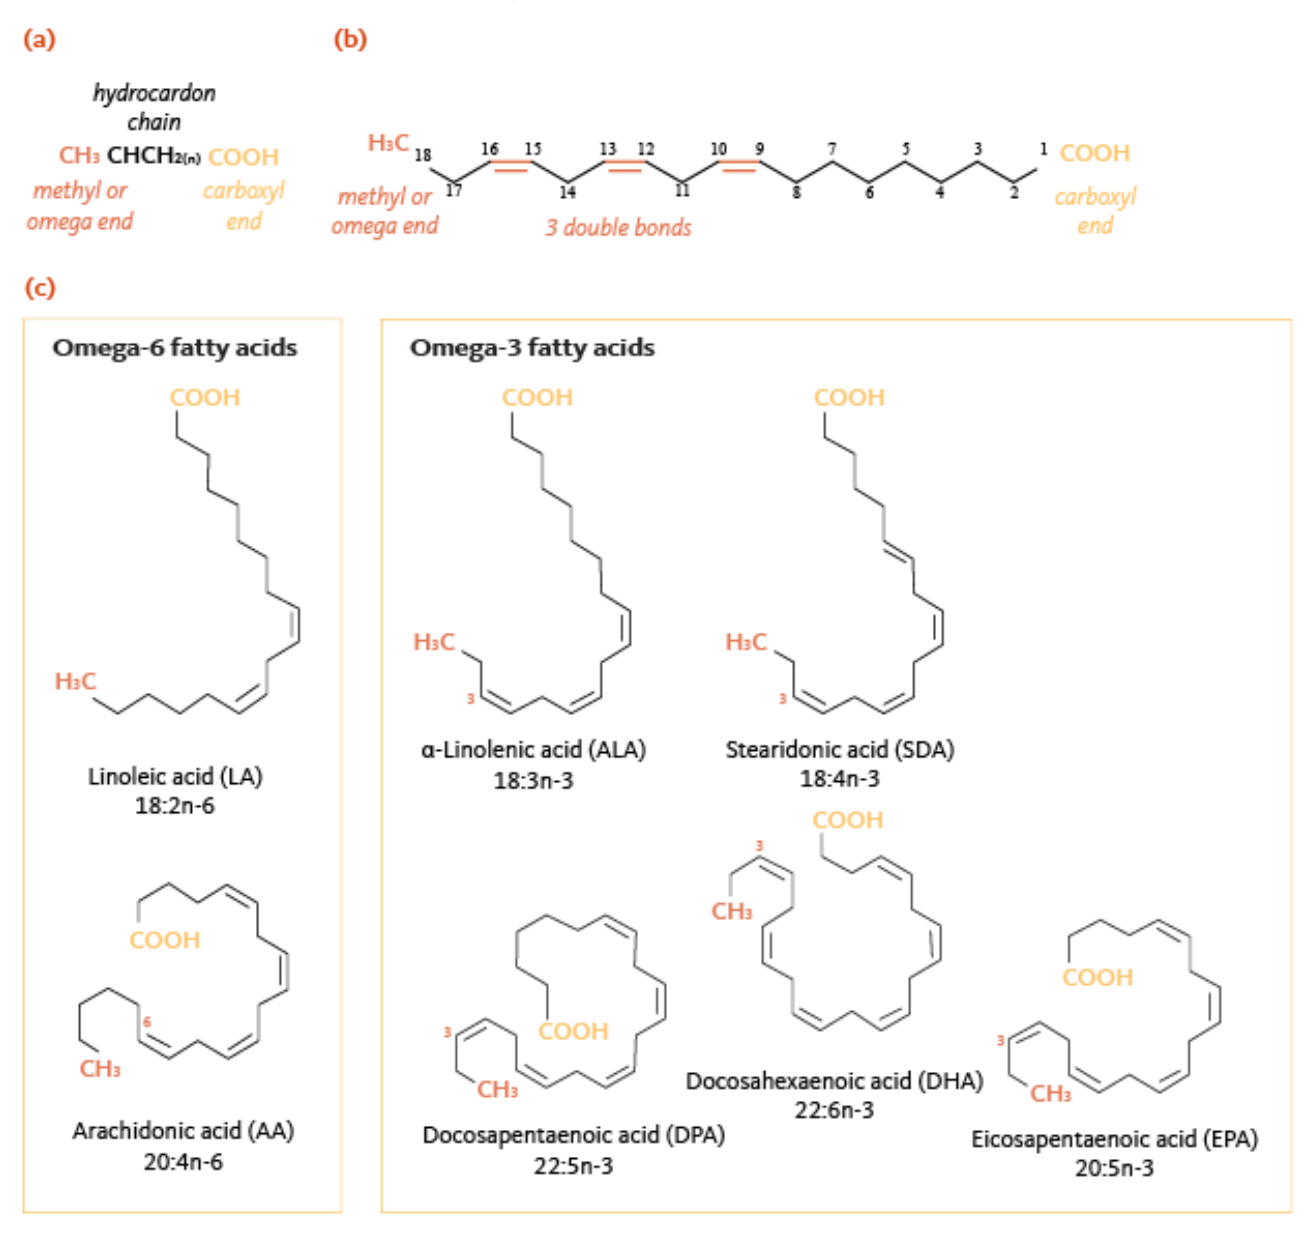
- Linoleic acid (LA), an omega-6 fatty acid, and α-linolenic acid (ALA), an omega-3 fatty acid, are considered essential fatty acids because they cannot be synthesized by humans. *(More information)*
- The long-chain omega-3 fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), can be synthesized from ALA, but due to low conversion efficiency, it is recommended to consume foods rich in EPA and DHA. *(More information)*
- Both omega-6 and omega-3 fatty acids are important structural components of cell membranes, serve as precursors to bioactive lipid mediators, and provide a source of energy. Long-chain omega-3 polyunsaturated fatty acids (PUFA in particular exert anti-inflammatory effects; it is recommended to increase their presence in the diet. *(More information)*
- Both dietary intake and endogenous metabolism influence whole body status of essential fatty acids. Genetic polymorphisms in fatty acid synthesizing enzymes can have a significant impact on fatty acid concentrations in the body. *(More information)*
- DHA supplementation during pregnancy may reduce the risks of early premature birth (birth before 34 weeks' gestation) and very low birth weight (<1.5 kg [<3 pounds 5 ounces]). *(More information)*
- DHA is important for visual and neurological development. However, supplementation with long-chain during pregnancy or early infancy appears to have no significant effect on children's visual acuity, neurodevelopment, and physical growth. *(More information)*
- Replacing saturated fat in the diet with omega-6 lowers total blood cholesterol; yet, randomized controlled trials have failed to demonstrate cardiovascular benefits in healthy people and people at risk for or with type 2 diabetes mellitus. Long-chain omega-3 PUFA supplementation may be useful to reduce mortality in patients with prevalent coronary heart disease (CHD) and in those with heart failure without preserved ventricular function. *(More information)*
- Increasing EPA and DHA intake may benefit individuals with type 2 diabetes mellitus, especially those with elevated serum triglycerides. However, evidence from large-scale randomized trials is insufficient to support the use of omega-3 PUFA supplements for cardiovascular disease prevention in those with type 2 diabetes. *(More information)*
- Observational studies have found fish intake to be associated with lower risks of cognitive deterioration and Alzheimer's disease, but it is not yet clear whether supplementation with marine-derived omega-3 PUFA can help prevent cognitive decline. *(More information)*
- Several omega-3 formulations have been approved by the US Food and Drug Administration for the indication of treating severe hypertriglyceridemia. *(More information)*
- Although omega-3 PUFA deficiency may not be uncommon in neurodevelopmental and neuropsychiatric disorders, there is little evidence to suggest that supplementation may be a beneficial adjunct in the management of affected individuals. *(More information)*
- The Food and Nutrition Board of the US Institute of Medicine (now the National Academy of Medicine) established adequate intakes (AI) for omega-6 and omega-3 fatty acids. *(More information)*

Introduction

Omega-6 and omega-3 fatty acids are polyunsaturated fatty acids (PUFA), meaning they contain more than one *cis* double bond (1). In all omega-6 (ω6 or n-6) fatty acids, the first double bond is located between the sixth and seventh carbon atom from the methyl end of the fatty acid. Likewise, all omega-3 fatty acids (ω3 or n-3) have at least one double bond between the third and fourth carbon atom counting from the methyl end of the fatty acid. Scientific abbreviations for fatty acids tell the reader something about their chemical structure. For example, the scientific abbreviation for α-linolenic acid (ALA) is 18:3n-3. The first part (18:3) tells the reader that ALA is an 18-carbon fatty acid with three double bonds, while the second part (n-3) tells the reader that the first double bond is in the n-3 position, which defines this fatty acid as an omega-3 (**Figures 1a & b**). Double bonds introduce kinks in the hydrocarbon chain that influence the structure and physical properties of the fatty acid molecule (**Figure 1c**).

Although humans and other mammals can synthesize saturated fatty acids and some monounsaturated fatty acids from carbon groups in carbohydrates and proteins, they lack the delta (Δ) 12 and Δ15 desaturase enzymes necessary to insert a *cis* double bond at the n-6 or the n-3 position of a fatty acid (1). Consequently, omega-6 and omega-3 fatty acids are essential nutrients. The parent fatty acid of the omega-6 series is linoleic acid (LA; 18:2n-6), and the parent fatty acid of the omega-3 series is ALA (**Figure 2** and **Table 1**). Humans can synthesize long-chain (20 carbons or more) omega-6 fatty acids, such as dihomo-γ-linolenic acid (DGLA; 20:3n-6) and arachidonic acid (AA; 20:4n-6), from LA and long-chain omega-3 fatty acids, such as eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3), from ALA (see Metabolism and Bioavailability).

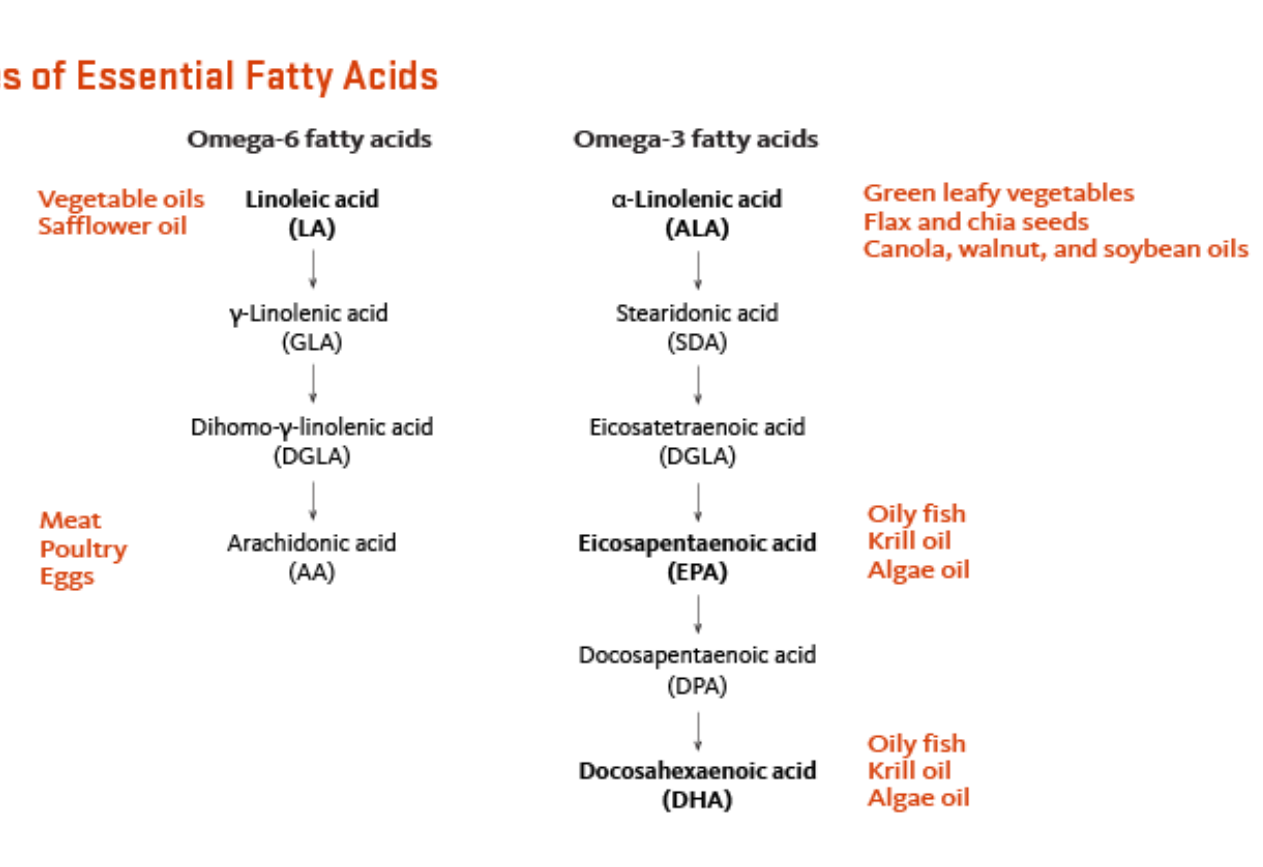
Figure 1. Chemical Structures of Fatty Acids



(a) The general structure of a fatty acid (22). (b) The chemical structure of α -linolenic acid (ALA), 18:3n-3. ALA has 18 carbon atoms (c) and 3 double bonds, the first of which is located 3 carbon atoms from the terminal methyl group (omega [ω] end). (c) The molecular structures of dietary omega-6 and omega-3 fatty acids. The presence of a double bond in the hydrocarbon chain of polyunsaturated fatty acids (PUFA) introduces a "kink" in the molecule, creating different secondary structures that influence physical properties (5).

[Figure 1a and 1b - Click to Enlarge] [Figure 1c - Click to Enlarge]

Figure 2. Classes of Essential Fatty Acids



Omega-6 (n-6) and omega-3 (n-3) fatty acids comprise the two classes of essential fatty acids (EFA). The parent compounds of each class, linoleic acid (LA) and α-linolenic acid (ALA) (bold font), give rise to longer chain derivatives inside the body. Due to low efficiency of conversion of ALA to the long-chain omega-3 PUFA, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), it is recommended to obtain EPA and DHA from additional sources. Dietary sources of the different long-chain PUFA are listed in the colored boxes (25).

Metabolism and Bioavailability

Prior to absorption in the small intestine, fatty acids must be hydrolyzed from dietary fats (triglycerides and phospholipids) by pancreatic enzymes (2). Bile salts must also be present in the small intestine to allow for the incorporation of fatty acids and other fat digestion products into mixed micelles. Fat absorption from mixed micelles occurs throughout the small intestine and is small intestine to allow for the incorporation of fatty acids and other fat digestion products into mixed micelles. Fat absorption from mixed micelles occurs throughout the small intestine and is 85%-95% efficient under normal conditions.

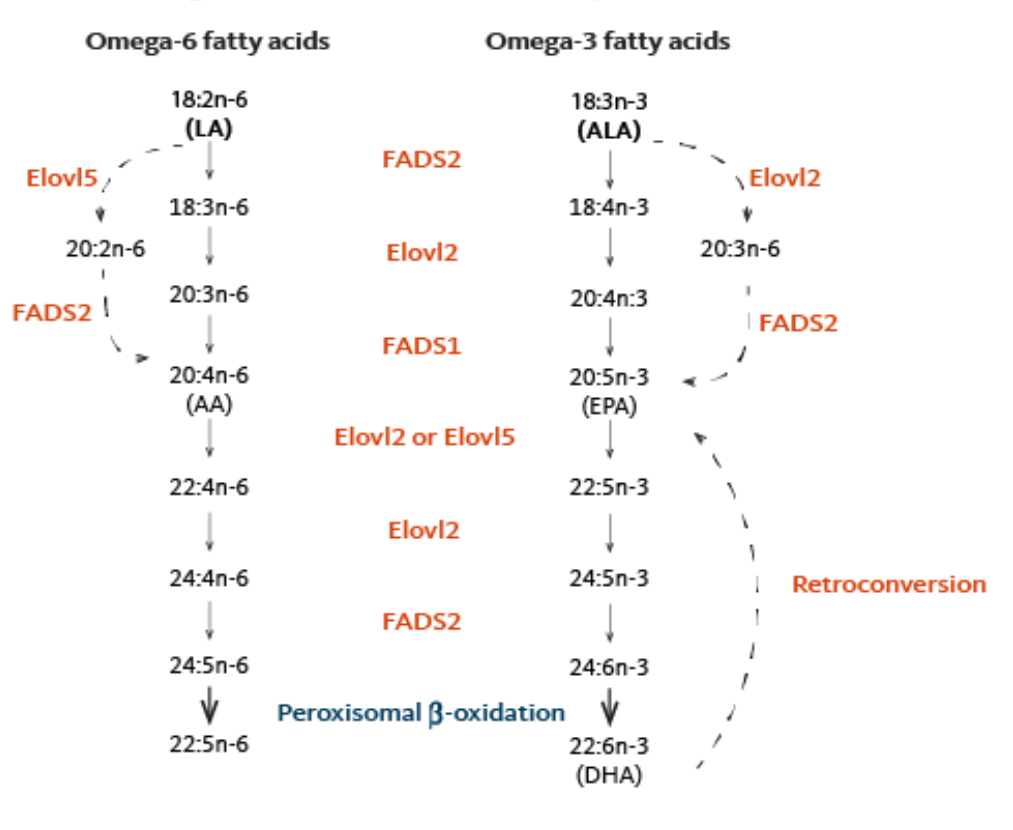
Concentrations of fatty acids in blood (i.e., whole blood, plasma, serum, and red blood cells) reflect both dietary intake and biological processes (3). Humans can synthesize longer omega-6 and omega-3 fatty acids from the essential fatty acids linoleic acid (LA) and α-linolenic acid (ALA), respectively, through a series of desaturation (addition of a double bond between two carbon atoms) and elongation (addition of two carbon atoms) reactions (**Figure 3**) (4, 5). LA and ALA compete for the same elongase and desaturase enzymes in the synthesis of longer polyunsaturated fatty acids (PUFA), such as arachidonic acid (AA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA).

Studies of ALA metabolism in healthy young men indicated that approximately 8% of dietary ALA was converted to EPA and 0%-4% was converted to docosahexaenoic acid (DHA) (6). In healthy young women, approximately 21% of dietary ALA was converted to EPA and 9% was converted to DHA (7). The better capacity to generate long-chain PUFA from ALA in young women compared to men is related to the effects of estrogen (8, 9). Although only the essentiality of ALA is recognized because it cannot be synthesized *de novo* by humans, the relatively low rate of ALA conversion into EPA and DHA suggests that these long-chain omega-3 PUFA may be considered conditionally essential nutrients.

In addition to gender differences, genetic variability in enzymes involved in fatty acid metabolism influences one's ability to generate long-chain PUFA. Two key enzymes in fatty acid metabolism are delta 6 desaturase (FADS2) and delta 5 desaturase (FADS1) (**Figure 3**) (10). Two common haplotypes (a cluster of polymorphisms) in the FADS genes differ dramatically in their ability to generate long-chain PUFA: haplotype D is associated with increased FADS activity (both FADS1 and FADS2) and higher conversion rate of fatty acid precursors (LA and ALA) to long-chain PUFA (EPA, GLA, DHA, and AA) (11). These FADS polymorphisms are relatively common in the population and may explain up to 30% of the variability in blood concentrations of omega-3 and omega-6 fatty acids among individuals (3).

Finally, DHA can be retro-converted to EPA and DPA at a low basal rate and following supplementation (**Figure 3**) (12). After supplementing omnivores (n=8) and vegetarians (n=12) for six weeks with an EPA-free preparation of DHA (1.62 g/day), EPA, DPA, and DHA concentrations increased in serum and platelet phospholipids (13). Based on the measured changes, the estimated percent retroconversion of DHA to EPA was 7.4%-11.4% (based on serum phospholipid data) and 12.3%-13.8% (based on platelet phospholipid data), with no significant difference between omnivores and vegetarians. Due to this nontrivial retroconversion efficiency, DHA supplementation may represent an alternative to fish oil to increase blood and tissue concentrations of EPA, DPA, and DHA (see Supplements) (5).

Figure 3. Desaturation and Elongation of Essential Fatty Acids



Humans can synthesize longer omega-6 and omega-3 fatty acids from the essential fatty acids LA and ALA through a series of desaturation (addition of a double bond) and elongation (addition of two carbon atoms) reactions that occur in microsomes. Delta-6 desaturase (FADS2) is considered the rate-limiting enzyme in this metabolic pathway. Retroconversion of DHA to EPA in peroxisomes occurs at low basal rates and following DHA supplementation (4, 5). *FADS2, delta-6 desaturase; FADS1, delta-5 desaturase; Elovl2, Elovl5, elongases.*

Biological Activities

Membrane structure and function

Omega-6 and omega-3 PUFA are important structural components of cell membranes. When incorporated into phospholipids, they affect cell membrane properties, such as fluidity, flexibility, permeability, and the activity of membrane-bound enzymes and cell-signaling pathways (14, 15). In addition to endogenous metabolism, dietary consumption of fatty acids can modify the composition and molecular structure of cellular membranes. Thus, increasing omega-3 fatty acid intake increases the omega-3 content of red blood cells, immune cells (16), atherosclerotic plaques (17), cardiac tissue (18), and other cell types throughout the body.

DHA is selectively incorporated into retinal cell membranes and postsynaptic neuronal cell membranes, suggesting it plays important roles in vision and nervous system function. In fact, DHA represents the predominant PUFA in the retina and neuronal cells (19).

Vision

DHA is found at very high concentrations in the cell membranes of the retina; the retina conserves and recycles DHA even when omega-3 fatty acid intake is low (20). Animal studies indicate that DHA is required for the normal development and function of the retina. Moreover, these studies suggest that there is a critical period during retinal development when inadequate DHA will result in permanent abnormalities in retinal function. Research indicates that DHA plays an important role in the regeneration of the visual pigment rhodopsin, which plays a critical role in the visual transduction system that converts light hitting the retina to visual images in the brain (21).

Nervous system

The phospholipids of the brain's gray matter contain high proportions of long-chain PUFA, suggesting they are important to central nervous system function (22). AA stimulates glucose uptake by cortical astrocytes, meaning that it is important for energy metabolism (23). AA and DHA also increase the release of acetylcholine, which enhances synaptic plasticity and memory, thereby improving learning abilities (24). Although trials of PUFA supplementation during pregnancy and/or early infancy failed to show cognitive improvements in offspring (see Disease Prevention), the availability of omega-3 and omega-6 fatty acids to the fetus and infants is essential for the growth of their brain and development of brain functions. There is compelling evidence to suggest that PUFA are essential to neuronal growth and synapse formation, and for appropriate neurotransmission (reviewed in 25).

Synthesis of lipid mediators

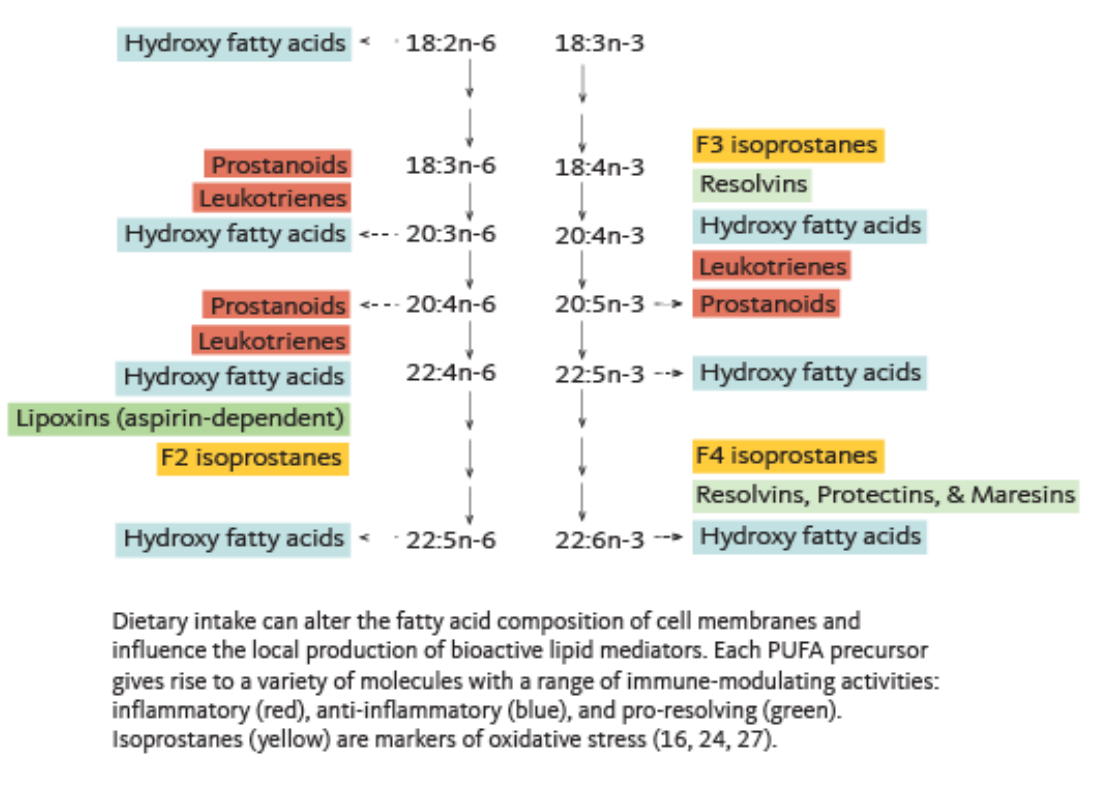
Oxylipins

Oxylipins are potent chemical messengers derived from PUFA. They play critical roles in immune and inflammatory responses. The most common oxylipins are eicosanoids that encompass numerous bioactive lipid mediators derived from 20-carbon ("eicosa-") AA. Following stimulation by hormones, cytokines, and other stimuli, PUFA bound to membrane phospholipids are released from cell membranes and become substrates for dodecanoid, eicosanoid, and docosanoid production. Oxylipin synthesis relies primarily on three families of enzymes: cyclooxygenases (COX), lipoxygenases (LOX), and cytochrome p450 mono-oxygenases (P450s) (26). From C_{18}-C_{22} precursors, COX enzymes produce prostaglandins, prostacyclins, and thromboxanes (collectively known as prostanoids); LOX produces leukotrienes and hydroxy fatty acids; and P450s produce hydroxyeicosatetraenoic acids ("HETEs") and epoxides (**Figure 4**).

Physiological responses to AA-derived eicosanoids differ from responses to EPA-derived eicosanoids. In general, EPA is a poor substrate for eicosanoid production and EPA-derives eicosanoids are less potent inducers of inflammation, blood vessel constriction, and coagulation than eicosanoids derived from AA (19, 27).

Nonetheless, it is an oversimplification to label all AA-derived eicosanoids as pro-inflammatory. AA-derived prostaglandins induce inflammation but also inhibit pro-inflammatory leukotrienes and cytokines and induce anti-inflammatory lipoxins, thereby modulating the intensity and duration of the inflammatory response via negative feedback (**Figure 4**) (17).

Figure 4. Bioactive Lipid Mediators Derived from Omega-6 and Omega-3 Fatty Acids



Dietary intake can alter the fatty acid composition of cell membranes and influence the local production of bioactive lipid mediators. Each PUFA precursor gives rise to a variety of molecules with a range of immune-modulating activities: inflammatory (red), anti-inflammatory (blue), and pro-resolving (green). Isoprostanes (yellow) are markers of oxidative stress (16, 24, 27).

[Figure 4 - Click to Enlarge]

Pro-resolving mediators

A separate class of PUFA-derived bioactive lipids, specialized pro-resolving mediators (SPMs), has been more recently identified (reviewed in 28). These molecules function as local mediators of the resolution phase of inflammation, actively turning off the inflammatory response. SPMs are derived from both omega-6 and omega-3 PUFA (**Figure 4**) (29). The S-series of SPMs results from the LOX-mediated oxygenation of EPA and DHA, giving rise to S-resolvins, S-protectins, and S-maresins. A second class of SPMs, the R-series, is generated from the aspirin-dependent acetylation of COX-2 and subsequent generation of aspirin-triggered SPMs from AA, EPA, and DHA. It appears that these mediators may explain many of the anti-inflammatory actions of omega-3 fatty acids that have been described (16, 30).

Isoprostanes

Isoprostanes are prostaglandin-like compounds that are formed by non-enzymatic, free radical-induced oxidation of any PUFA with three or more double bonds (**Figure 4**) (26). Because they are produced upon exposure to free radicals, isoprostanes are often used as markers for oxidative stress. In contrast to prostanoids, isoprostanes are synthesized from esterified PUFA precursors and remain bound to the membrane phospholipid until cleaved by PLA_2 and released into circulation. In addition to being used as markers of oxidative stress, isoprostanes may also function as inflammatory mediators, exerting both pro- and anti-inflammatory effects (26).

Regulation of gene expression

PUFA are pleiotropic regulators of cell function. They can regulate gene expression directly by interacting with transcription factors or indirectly by influencing membrane lipid composition and cell signaling pathways.

The results of cell culture and animal studies indicate that omega-6 and omega-3 fatty acids can modulate the expression of a number of genes, including those involved with fatty acid metabolism and inflammation (31, 32). Omega-6 and omega-3 fatty acids regulate gene expression by interacting with specific transcription factors, such as peroxisome proliferator-activated receptors (PPARs) (33). In many cases, PUFA act like hydrophobic hormones (e.g., steroid hormones) to control gene expression and bind directly to receptors like PPARs. These ligand-activated receptors then bind to the promoters of genes and function to increase/decrease transcription.

In other cases, PUFA regulate the abundance of transcription factors inside the cell's nucleus (14). Two examples include NFϰB and SREBP-1. NFϰB is a transcription factor involved in regulating the expression of multiple genes involved in inflammation. Omega-3 PUFA suppress NFϰB nuclear content, thus inhibiting the production of inflammatory eicosanoids and cytokines. SREBP-1 is a major transcription factor controlling fatty acid synthesis, both *de novo* lipogenesis and PUFA synthesis. Dietary PUFA can suppress SREBP-1, which decreases the expression of enzymes involved in fatty acid synthesis and PUFA synthesis. In this way, dietary PUFA function as feedback inhibitors of all fatty acid synthesis.

By altering cell membrane fluidity, fatty acids can interfere with the activity of membrane receptor systems and thus indirectly influence signaling pathways and gene expression (34).

Deficiency

Essential fatty acid deficiency

Clinical signs of essential fatty acid deficiency include a dry scaly rash, decreased growth in infants and children, increased susceptibility to infection, and poor wound healing (35). Omega-3, omega-6, and omega-9 fatty acids compete for the same desaturase enzymes. The desaturase enzymes show preference for the different series of fatty acids in the following order: omega-3 > omega-6 > omega-9. Consequently, synthesis of the omega-9 fatty acid eicosatrienoic acid (20:3n-9, mead acid, or 5,8,11-eicosatrienoic acid) increases only when dietary intakes of omega-3 and omega-6 fatty acids are very low; therefore, mead acid is one marker of essential fatty acid deficiency (36). A plasma eicosatrienoic acid:arachidonic acid (triene:tetraene) ratio greater than 0.2 is generally considered indicative of essential fatty acid deficiency (35, 37). In patients who were given total parenteral nutrition containing fat-free, glucose-amino acid mixtures, biochemical signs of essential fatty acid deficiency developed in as little as 7 to 10 days (38). In these cases, the continuous glucose infusion resulted in high circulating insulin concentrations, which inhibited the release of essential fatty acids stored in adipose tissue. When glucose-free amino acid solutions were used, parenteral nutrition up to 14 days did not result in biochemical signs of essential fatty acid deficiency. Essential fatty acid deficiency has also been found to occur in patients with chronic fat malabsorption (39) and in patients with cystic fibrosis (40). It has been proposed that essential fatty acid deficiency may play a role in the pathology of protein-energy malnutrition (36).

Omega-3 fatty acid deficiency

At least one case of isolated omega-3 fatty acid deficiency has been reported. A young girl who received intravenous lipid emulsions with very little ALA developed visual problems and sensory neuropathy; these conditions were resolved when she was administered an emulsion containing more ALA (41). Isolated omega-3 fatty acid deficiency does not result in increased plasma triene:tetraene ratios, and skin atrophy and dermatitis are absent (1). Plasma DHA concentrations decrease when omega-3 fatty acid intake is insufficient, but no accepted plasma omega-3 fatty acid or eicosanoid concentrations indicative of impaired health status have been defined (1). Studies in rodents have revealed significant impairment of n-3 PUFA deficiency on learning and memory (42, 43), prompting research in humans to assess the impact of omega-3 PUFA on cognitive development and cognitive decline (see Cognitive and visual development and Alzheimer's disease).

Omega-3 index

The omega-3 index is defined as the amount of EPA plus DHA in red blood cell membranes expressed as the percent of total red blood cell membrane fatty acids (44). The EPA + DHA content of red blood cell membranes correlates with that of cardiac muscle cells (45, 46), and several observational studies indicate that a lower omega-3 index is associated with an increased risk of coronary heart disease mortality (47). It is therefore proposed that the omega-3 index be used as a biomarker for cardiovascular disease risk, with suggested cutoffs as follows: high risk, <4%; intermediate risk, 4%-8%; and low risk, >8% (48).

Supplementation with EPA + DHA from fish oil capsules for approximately five months dose-dependently increased the omega-3 index in 115 healthy, young adults (ages, 20-45 years), validating the use of the omega-3 index as a biomarker of EPA + DHA intake (49). Before the omega-3 index can be used in routine clinical evaluation, however, clinical reference values in the population must be established (50). Additionally, fatty acid metabolism may be altered in certain disease states, potentially making the omega-3 index less relevant for some cardiovascular conditions (5).

Disease Prevention

Pregnancy and early childhood developmental outcomes

Supplementation during pregnancy

Effect on pregnancy-associated conditions and neonatal outcomes: The results of randomized controlled trials during pregnancy suggest that omega-3 polyunsaturated fatty acid (PUFA) supplementation does not decrease the incidence of gestational diabetes and preeclampsia (51-54) but may result in modest increases in length of gestation, especially in women with low omega-3 fatty acid consumption. A 2006 meta-analysis of six randomized controlled trials in women with low-risk pregnancies found that omega-3 PUFA supplementation during pregnancy resulted in an increased length of pregnancy by 1.6 days (55). A 2007 meta-analysis of randomized controlled trials in women with high-risk pregnancies found that supplementation with long-chain PUFA did not affect pregnancy duration or the overall incidence of premature births (birth before 37 weeks' gestation) but decreased the incidence of early premature births (birth before 34 weeks' gestation; 2 trials, 291 participants) (56). Analyses of the secondary outcomes of the 2010 DHA to Optimize Mother-Infant Outcome (DOMInO) trial in 2,399 participants showed that supplementation with DHA-enriched fish oil capsules (800 mg/day of DHA and 100 mg/day of EPA) during pregnancy (from <21 gestational weeks until birth) reduced the risk of early premature birth but increased the risk of obstetrical interventions like the need for induction or cesarean section, when compared to supplementation with DHA-free vegetable oil capsules (57). A 2016 meta-analysis of trials found evidence to suggest that omega-3 PUFA supplementation during pregnancy reduced the overall risk of prematurity and the risk of early premature births, increased gestational age at delivery and birth weight, and had no effect on the risks of perinatal death and low Apgar scores at 1 minute post birth (58). A dose-response analysis found a continuous reduction of the risks of early premature birth (birth before 34 weeks' gestation) and very low birth weight (birth weight <1,500 g) with daily doses of DHA supplement up to at least 600 mg during pregnancy (59). There is currently limited evidence to support a role for omega-3 supplementation in the prevention of recurrent intrauterine growth restriction (IUGR) (60) or recurrent preterm birth (61).

Effect on children's cognitive and visual development: The effect of maternal omega-3 long-chain PUFA supplementation on early childhood cognitive and visual development was summarized in a 2013 systematic review and meta-analysis (62). Included in this assessment were 11 randomized controlled trials (a total of 5,272 participants) that supplemented maternal diet with omega-3 long-chain PUFA during pregnancy or both pregnancy and lactation. Results regarding visual outcomes (eight trials) could not be pooled together due to variability in assessments; overall, four of six trials had null findings and the remaining two trials had very high rates of attrition. Cognitive outcomes (nine trials) included the Developmental Standard Score (DSS; in infants, toddlers, and preschoolers) or Intelligence Quotient (IQ; in children) and other aspects of neurodevelopment, such as language, behavior, and motor function. No differences were found between DHA and control groups for cognition measured with standardized psychometric scales in infants (<12 months), toddlers (12-24 months), and school-aged children (5-12 years); preschool children (2-5 years) in the DHA treatment group had a substantially higher DSS score compared to controls. The authors noted that many of the trials of long-chain PUFA supplementation in pregnancy had methodological weaknesses (e.g., high rates of attrition, small sample sizes, high risk of bias, multiple comparisons), limiting the confidence and interpretation of the pooled results. Of note, a seven-year follow-up of the DOMInO trial is currently underway to assess the effect of DHA supplementation during pregnancy on child IQ and various measures of cognitive development (e.g., executive functioning, memory, language) (63).

Effect on children's body composition: The follow-up of 1,531 children whose mothers were randomized to supplemental DHA (800 mg/day) or a control during the second half of pregnancy in the DOMInO trial showed no effect of maternal DHA supplementation on the body mass index (BMI)-for-age z score and percentage of body fat of their children at three and five years of age (64). Measures of insulin resistance in 5-year-old children were unexpectedly higher in children whose mothers were in the DHA group than in those whose mothers were in the control group (64). Further analyses conducted in a subset of children (252) at age seven years again showed no effect of DHA supplementation on BMI z score, percentage of body fat, height, weight, and waist/hip circumference (65). Current evidence from 10 randomized controlled trials primarily conducted in high-income countries (all but one) suggests no influence of maternal supplementation with long-chain PUFA on the body composition and anthropometry of the offspring (66).

Effect on children's risk of allergies and asthma: A 2018 meta-analysis of randomized controlled trials in 2,047 children followed for six months to 16 years found a 19% lower risk of wheezing and/or asthma with maternal supplementation of omega-3 PUFA (primarily EPA and DHA) from as early as the 20th week of gestation until delivery (67). However, there was no effect of prenatal supplementation when the analysis was restricted to the three trials that reported on the incidence of childhood asthma only (67). Another meta-analysis of nine trials in 3,637 children, including three trials in which maternal supplementation with omega-3 PUFA continued after birth, found no effect of prenatal supplements on the risk of any allergy (three trials), the risk of wheeze and/or asthma (seven trials), the risk of eczema (six trials), the development of allergic rhinitis (two trials), and the risk of food allergy (three trials) in children (68). There was, however, some evidence to suggest that prenatal supplementation could lower the incidence of sensitization to specific allergens, namely egg (three trials; -46%) and peanut (two trials; -38%) (68).

Supplementation to breast-feeding mothers

A 2015 systematic review and meta-analysis summarized the results of eight randomized controlled trials that examined the effect of maternal supplementation with long-chain PUFA during either pregnancy and lactation or lactation only on the development and growth of their infants over the first two years of life and beyond (69). All studies were conducted in high-income countries. No differences between long-chain PUFA supplementation and control were observed in terms of language development, intelligence or problem-solving ability, psychomotor development, and anthropometric measurements (weight, length/height, head circumference, BMI, fat mass distribution) (69).

Supplementation in infants

The last trimester of pregnancy and first six months of postnatal life are critical periods for the accumulation of DHA in the brain and retina (70). Human milk contains a mixture of saturated fatty acids (~46%), monounsaturated fatty acids (~41%), omega-6 PUFA (~12%), and omega-3 PUFA (~1.3%) (71). Although human milk contains DHA in addition to ALA and EPA, ALA was the only omega-3 fatty acid present in conventional infant formulas until the year 2001. Although infants can synthesize DHA from ALA, they generally cannot synthesize enough to prevent declines in plasma and cellular DHA concentrations without additional dietary intake. Therefore, it was proposed that infant formulas be supplemented with enough DHA to bring plasma and cellular DHA concentrations of formula-fed infants up to those of breast-fed infants (72).

All infants: Although formulas enriched with DHA raise plasma and red blood cell DHA concentrations in preterm and term infants, the results of randomized controlled trials examining measures of visual acuity and neurological development in infants fed formula with or without added DHA have been mixed. For instance, a 2012 meta-analysis of randomized controlled trials (12 trials, 1,902 infants) comparing long-chain PUFA-supplemented and unsupplemented formula, started within one month of birth, found no effect of long-chain PUFA supplementation on infant cognition assessed at approximately one year of age (73). A lack of effect was observed regardless of the dose of long-chain PUFA or the prematurity status of the infant. With respect to visual acuity, a 2013 meta-analysis of randomized controlled trials (19 trials, 1,949 infants) found a beneficial effect of long-chain PUFA-supplemented formula, started within one month of birth, on infant visual acuity up to 12 months of age (74). Notably, two different types of visual acuity assessment were evaluated in the meta-analysis. Visual acuity assessed by using the Visually Evoked Potential (10 trials, 852 infants) showed a significant positive effect of long-chain PUFA-supplemented formula at 2, 4, and 12 months of age. When assessed by the Behavioral Method (12 trials, 1,095 infants), a significant benefit of long-chain PUFA-supplemented formula on visual acuity was found only at the age of two months. No moderating effects of dose or prematurity status were observed.

Preterm infants: A few trials have been specifically conducted in preterm infants. This is the case of the DHA for the Improvement of Neurodevelopmental Outcome (DINO) trial that initially enrolled 657 very preterm infants (born <33 gestational weeks) in five Australian hospitals (75). The aim of the trial was to examine the effect of enteral feeds with either high DHA (1% of total fatty acids) or standard DHA level (0.3% of total fatty acids) to preterm infants from age 2 to 4 days of life until term's corrected age (mean duration, 9.4 weeks) on their mental and psychomotor development, assessed at 18 months' and 7 years' corrected ages. At the 18-month follow-up, there was no difference in mean Mental Development Index (MDI) and Psychomotor Development Index (PDI) test scores between high-DHA and standard-DHA groups; yet, better MDI scores in girls fed high-DHA versus those fed standard-DHA feeds were reported in subgroup analyses (75). Post-hoc analyses also suggested fewer cases with delayed mental development among girls and infants weighing <1,250 kg at birth in the high- versus standard-DHA group (75). Follow-up at 7 years' corrected age showed no difference between groups in measures of IQ and cognitive development, including attention, short-term verbal memory and learning ability, executive functioning, visual perception, and academic achievement (76). A 2016 systematic review of 17 trials found little evidence to suggest that supplementing preterm infants with long-chain PUFA (primarily AA and DHA) improved measures of visual acuity, neurodevelopment, and physical growth during infancy (77).

Cardiovascular disease

Omega-6 fatty acids

Linoleic acid (LA) is the most abundant dietary PUFA and accounts for approximately 90% of dietary omega-6 PUFA intake (78).

Observational studies: A pooled analysis of 13 prospective cohort studies, encompassing 310,602 individuals and 12,479 coronary heart disease (CHD) events (of which resulted in 5,882 CHD deaths) over follow-up periods of 5.3 to 30 years, found higher LA intakes to be associated with a 15% lower risk of CHD events and a 21% lower risk of CHD mortality (79). A dose-response analysis found that replacing 5% of energy from saturated fatty acids with LA was associated with a 9% lower risk of coronary events and a 13% lower risk of coronary deaths (79). A 2019 meta-analysis of 30 prospective cohort studies in 68,659 participants found that individuals in the highest versus lowest quintile of LA concentrations in tissues (primarily blood compartments) had a 23% lower risk of cardiovascular mortality (80). No associations were found between LA concentrations in tissues and the risks of CHD, ischemic stroke, or total cardiovascular disease (80).

Randomized controlled trials: Taking into consideration the results from four randomized controlled trials (81-85) that compared the effects of diets either high in saturated fatty acids or PUFA over at least two years, a 2016 systematic review and presidential advisory from the American Heart Association concluded that lowering saturated fat intake and replacing it with vegetable oil rich in PUFA (primarily soybean oil) could reduce the risk of CHD by 29% (86). Of note, these trials were conducted in the 1960s and 1970s, when the use of cholesterol-lowering drug statin was not widespread and the saturated fat content in diets was higher; all but one trial (84, 85) were in men with diagnosed cardiovascular disease (CVD). Among these four trials, the Oslo Diet-Heart Study (83) increased both omega-3 and omega-6 PUFA intake, and the Finnish Mental Hospital Study (84, 85) used a cross-over design — both trials were excluded from a Cochrane systematic review of 19 randomized controlled trials that examined the effect of increasing omega-6 PUFA intake on CVD outcomes (87). Of these 19 trials, seven assessed the effect of supplemental γ-linolenic acid (GLA) and 12 assessed the effect of substituting dietary LA for saturated or monounsaturated fatty acids. The pooled analysis of studies showed no effect of increasing omega-6 intake on the risks of CHD or CVD events, major adverse cardiac and cerebrovascular events, myocardial infarction (MI), stroke, CVD mortality, or all-cause mortality (low-quality evidence) (87). Moreover, many trials that examined the effect of replacing saturated fatty acids with mostly omega-6 PUFA may not have been adequately controlled. For example, in some trials, only the experimental group (the high omega-6 PUFA group) received dietary advice regarding more than just replacing saturated fatty acids by omega-3 PUFA, e.g., to avoid dietary sources of *trans* fatty acids and processed foods, to consume more whole-plant foods, to lower sugar consumption, to increase consumption of fish and shellfish, which could have biased the results (88). Additionally, a recent meta-analysis of trials with low risk of bias (i.e., free of differences between intervention and control groups other than those under examination) showed no evidence of an effect of substituting omega-6 PUFA for saturated fatty acids on the risks of major CHD events (MI and sudden death), total CHD events, CHD mortality, and all-cause mortality (88).

Yet, replacing dietary saturated fatty acids with omega-6 PUFA was consistently found to lower total blood cholesterol concentrations (87, 89). In fact, LA has been shown to be the most potent fatty acid for lowering total cholesterol when substituted for dietary saturated fatty acids (90). The potential mechanisms by which LA reduces blood cholesterol include (1) the upregulation of LDL receptor and redistribution of LDL-cholesterol from plasma to tissue, (2) the increase in bile acid production and cholesterol catabolism, and (3) the decreased VLDL-to-LDL conversion (91). However, if substituting omega-6 PUFA for saturated fatty acids can reduce blood cholesterol, the most recent systematic reviews and meta-analyses have failed to find evidence of clinical cardiovascular benefits (see above) (87, 88, 92).

Omega-3 fatty acids

Observational studies: A meta-analysis of 17 prospective and two retrospective cohort studies in 45,637 generally healthy participants found that circulating concentrations of α-linolenic acid (ALA) and longer chain omega-3 PUFA (i.e., eicosapentaenoic acid [EPA], docosapentaenoic acid [DPA], docosahexaenoic acid [DHA]) were inversely associated with the risk of fatal coronary heart disease (CHD) (93).

Several observational studies also examined the relationship between dietary ALA intake and the risk of CHD. A 2018 meta-analysis of 14 prospective cohort studies in a total of 345,202 participants free of cardiovascular disease (CVD) evaluated the risk of composite CHD outcomes (combining different CHD events) and fatal CHD in relation to dietary consumption of ALA (94). Overall, the pooled analysis found a 9% lower risk of composite CHD outcomes and a 15% lower risk of fatal CHD with higher ALA exposure (94). Further, a number of prospective cohort studies have examined the consumption of fish, rich in long-chain omega-3 PUFA (mainly EPA and DHA), in relation to various cardiovascular events and mortality. A 2018 review of the evidence and advisory from the American Heart Association concluded that seafood intake was associated with modestly lower risks of CHD, ischemic stroke, and sudden cardiac death, and noted a greater benefit when intake went from zero to one or two seafood meals per week and when seafood was substituted for less healthy options like processed meat (95). In contrast, recently published meta-analyses of prospective cohort studies found little evidence of inverse associations between fish consumption and either CHD or stroke (96, 97). Higher fish consumption was found to be associated with lower risks of myocardial infarction (MI) (98) and congestive heart failure (96). In addition, one meta-analysis of 12 prospective cohort studies found a 6% lower risk of all-cause mortality with the highest versus lowest level of fish consumption (99). Yet, another meta-analysis found no association between fish intake and all-cause mortality but a 4% lower risk of CVD mortality for each 20-g/day increment in fish intake (100).

The potential cardiovascular benefit of seafood consumption appears to be tightly linked to the type of seafood (e.g., fatty or lean fish), the way it is prepared (e.g., baked, broiled, or fried), the presence of toxic metals and environmental contaminants, and the habitual level of consumption (high versus low) — these factors may be confounding the results reported in observational studies and pooled analyses (95). Although seafood is a good source of long-chain omega-3 PUFA, health benefits associated with fish consumption could be attributed to the presence of other nutritional factors (e.g., micronutrients and high-quality protein) and that seafood consumption is usually a marker of higher socioeconomic status, as well as healthy lifestyles (101, 102).

Randomized controlled trials: A 2018 Cochrane systematic review assessed the evidence for a cardioprotective effect of ALA and long-chain omega-3 PUFA in individuals either at low or high risk of CVD (103). Moderate-to-high quality evidence from randomized controlled trials (of at least 12 months) suggested no effect of omega-3 PUFA (either supplemented, enriched in meals, or advised to be consumed) on the risk of CHD events, CVD events, arrhythmia, stroke, CHD mortality, CVD mortality, or all-cause mortality. There was also no evidence of an effect on secondary outcomes, including major adverse cerebrovascular or cardiovascular events, MI, sudden cardiac death, angina pectoris, heart failure, revascularization, peripheral arterial disease, and acute coronary syndrome (103). A 2017 review and advisory from the American Heart Association found no evidence to suggest a benefit of long-chain omega-3 PUFA supplementation for the prevention of cardiovascular mortality in patients with or at risk of type 2 diabetes mellitus, the prevention of CHD in patients with atherosclerotic disease (e.g., with prior stroke, peripheral vascular disease, diabetes, hypercholesterolemia), the prevention of stroke in patients with or without a history of stroke, and the prevention of atrial fibrillation in patients with prior atrial fibrillation or in those undergoing cardiac surgery (104). There was some evidence to suggest that supplementation with long-chain omega-3 PUFA in patients with prior clinical CHD might reduce the risk of CHD death, possibly because of a reduction in the risk of ischemia-induced sudden cardiac death (104).

Hypertriglyceridemia (borderline high: serum triglycerides 150-199 mg/dL; high: serum triglycerides >200 mg/dL) is an independent risk factor for cardiovascular disease (105). Numerous controlled clinical trials have demonstrated that increasing intakes of EPA and DHA significantly lower serum triglyceride concentrations (103). The triglyceride-lowering effects of EPA and DHA increase with dose (106), but clinically meaningful reductions in serum triglyceride concentrations have been demonstrated at doses of 2 g/day of EPA + DHA (107). Although long-chain omega-3 PUFA can reduce triglyceride concentrations, they have no effect on total cholesterol, LDL-cholesterol, or HDL-cholesterol in blood (103). Of note, the mechanisms by which long-chain omega-3 PUFA supplements may reduce CHD death are unlikely to involve a lowering of triglycerides as doses used in the studies (~1 g/day) were generally too low (104). Some studies in cell culture indicated that long-chain omega-3 PUFA may decrease the excitability of cardiac muscle cells (myocytes) by modulating ion channel conductance, which would be consistent with anti-arrhythmic effects observed in animal models (see also Hypertriglyceridemia) (108, 109).

Summary

Replacing dietary saturated fatty acids with omega-6 PUFA lowers total blood cholesterol, yet there is no convincing evidence of an effect of omega-6 PUFA on the risk of major CVD events. Although evidence supports the adoption of a heart-healthy dietary pattern that includes two servings of seafood per week (95), supplementation with long-chain omega-3 fatty acids is unlikely to result in cardiovascular benefits in generally healthy people with a low CVD risk or in individuals at risk of or with type 2 diabetes mellitus (104). In its recommendations regarding omega-3 fatty acids and cardiovascular disease (see Intake Recommendations), the American Heart Association indicates that long-chain omega-3 PUFA supplementation may be useful to reduce mortality in patients with prevalent CHD (e.g., who suffered a recent MI) and in those with heart failure without preserved ventricular function (104).

Cardiometabolic risk factors in individuals with diabetes mellitus

Type 2 diabetes mellitus: Cardiovascular disease is the leading cause of death in individuals with diabetes mellitus. The dyslipidemia typically associated with diabetes is characterized by a combination of hypertriglyceridemia (serum triglycerides >200 mg/dL), low HDL-cholesterol, and abnormal LDL-cholesterol (110). Lipid-lowering therapy to normalize diabetic dyslipidemia and reduce cardiovascular risk includes lifestyle modification and medications — particularly the use of cholesterol-lowering statins (111, 112). Additionally, achieving glucose control in people with type 2 diabetes has been shown to decrease the occurrence of major microvascular and macrovascular events (113).

A 2014 meta-analysis of 19 randomized controlled trials, including 24,788 individuals with either impaired glucose metabolism or type 2 diabetes mellitus, found that long-chain omega-3 PUFA supplementation (doses, 360-10,000 mg/day; for 6 weeks to 6 years) lowered serum triglyceride concentrations by 0.25 mmol/L but had no substantial effect on total cholesterol, LDL-cholesterol, or HDL-cholesterol (114). There was also no significant effect on HbA1c, fasting glucose, blood pressure, heart rate, or a measure of endothelial function. Four trials that lasted over a year reported on cardiovascular outcomes, including mortality. The pooled analysis of these trials found no effect of supplementation with omega-3 PUFA on the risk of major cardiovascular events, cardiovascular mortality, all-cause mortality, or a composite endpoint of all-cause mortality and hospitalization for a cardiovascular cause. It is worth noting that two of these trials — the Alpha Omega Trial (115) and the ORIGIN trial (116) — included a high proportion of participants who took cardiovascular medications (i.e., cholesterol-lowering statins) (114). Another meta-analysis of 45 randomized controlled trials in 2,674 participants with type 2 diabetes found that supplementation with omega-3 (400-1,800 mg/day for 2 weeks to 2 years) led to small decreases in blood concentrations of triglycerides, VLDL-triglycerides, LDL-cholesterol, and vLDL-cholesterol (117). There was no evidence of an effect on total cholesterol, HDL-cholesterol, non-esterified fatty acids, apolipoprotein-A1, and apolipoprotein-B. There was a reduction in circulating concentrations of pro-inflammatory cytokines, TNF-α and IL-6, in response to omega-3 supplementation, yet not of C-reactive protein (CRP) — a marker of low-grade inflammation. Omega-3 PUFA supplementation had no effect on systolic or diastolic blood pressure. Finally, a small decrease in HbA1c was reported in response to supplemental omega-3 fatty acids, yet there was no effect on other indicators of glycemic control, especially fasting glucose, fasting insulin, connecting (C-) peptide, and a measure of insulin resistance (117).

Lifestyle changes involving dietary modifications, such as the substitution of healthy fats (mono- and poly-unsaturated fatty acids) for saturated and *trans* fats, are recommended to reduce the risk of cardiovascular disease in people with type 2 diabetes mellitus (118). In their most recent updated recommendations on the prevention of cardiovascular disease in adults with type 2 diabetes, the American Diabetes Association and American Heart Association found insufficient evidence from large-scale randomized trials in individuals with type 2 diabetes to support the use of omega-3 fatty acid supplements (combined with a heart-healthy diet) in the prevention of cardiovascular events (118).

Gestational diabetes: Poor glycemic control during pregnancy, whether due to type 1 diabetes, type 2 diabetes, or gestational diabetes, increases the risk of fetal anomalies, preeclampsia, spontaneous abortion, stillbirth, macrosomia, neonatal hypoglycemia, and neonatal hyperbilirubinemia (119). Diabetes during pregnancy is also associated with a higher risk of metabolic disorders in offspring later in life (119). A team of investigators in Iran examined the effect of omega-3 PUFA supplementation during pregnancy, beginning at 24 to 28 weeks' gestation for six weeks, in women with gestational diabetes. Overall, there was evidence of beneficial effects of 1,000 mg/day of omega-3 alone (120) or together with vitamin E (121) or vitamin D (122) on markers of glucose homeostasis and, to a lesser extent, on markers of oxidative stress and inflammation and blood lipid profile. In one randomized, placebo-controlled trial in 60 women with gestational diabetes, supplementation with omega-3 fatty acids and vitamin E reduced the risk of neonatal hyperbilirubinemia yet had no effect on the rate of cesarean section, need for insulin therapy, maternal hospitalization, newborns' hospitalization, gestational age, birth size, and Apgar score (122).

Current recommendations by the American Diabetes Association for the management of gestational diabetes encourage the development of an individualized nutrition plan between a woman and a registered dietitian, highlighting the importance of the amount and type of carbohydrates in the diet (119). The use of omega-3 supplements in the management of gestational diabetes is not currently under consideration.

Type 2 diabetes mellitus

A meta-analysis of 13 randomized, controlled feeding trials that substituted plant-derived PUFA (primarily linoleic acid [LA]) for saturated fatty acids or carbohydrates for 3 to 16 weeks in generally healthy adults showed a decrease in fasting insulin concentration and insulin resistance but no effect on fasting glucose concentration (123). Most studies used a mixture of omega-3 and omega-6 PUFA in the form of plant-derived oils such that potential differences in effect between them could not be examined.

A meta-analysis of 20 prospective cohort studies conducted in 10 countries, in a total of 39,740 participants free from diabetes at baseline, examined biomarkers of omega-6 intake in relation to the risk of developing type 2 diabetes mellitus (124). LA ranged from 8.3% of total fatty acids in erythrocyte phospholipids to 54.5% in plasma cholesterol esters. The lowest percentage of arachidonic acid (AA) was found in adipose tissue (0.3%) and the highest in erythrocyte phospholipids (17.0%). The highest versus lowest concentration of LA markers in each compartment (phospholipids, plasma or serum, cholesterol esters) except adipose tissue was associated with a 35% lower risk of type 2 diabetes. In contrast, only AA in plasma or serum was inversely associated with the risk of type 2 diabetes (124). If LA concentration in blood and adipose tissue can provide an objective assessment of dietary LA intake (125), these results suggest that dietary LA may be important for glycemic control and diabetes prevention.

Metabolic syndrome

A 2019 meta-analysis of 13 observational (9 cross-sectional, 2 case-control, 1 nested case-control, and 1 prospective cohort; 36,542 participants) studies showed higher concentrations of omega-3 in blood and adipose tissue and higher level of omega-3 intake to be associated with a lower risk of metabolic syndrome (126). No association was found between tissue omega-6 concentration or dietary omega-6 intake level and the risk of metabolic syndrome (126).

Cognitive decline and Alzheimer's disease

Alzheimer's disease is the most common cause of dementia in older adults (127). Alzheimer's disease is characterized by the formation of amyloid plaque in the brain and nerve cell degeneration. Disease symptoms, including memory loss and confusion, worsen over time (128).

Observational studies: Several observational studies have examined dietary fish and PUFA consumption in relation to risks of cognitive decline, dementia, and Alzheimer's disease. The pooled analysis of five large prospective cohort studies (Three-City Study, Nurses' Health Study, Women's Health Study, Chicago Health and Aging Project, and Rush Memory and Aging Project) that followed a total of 23,688 older (ages, ≥65 years) participants (88% women) for 3.9 to 9.1 years found slower rates of decline in episodic memory and global cognition with increasing fish intakes (129). Previous studies have suggested that the effect of fish or PUFA consumption on cognition may be dependent on apolipoprotein E (APOE) genotype (130, 131). Of three common APOE alleles (epsilon 2 [ε2], ε3, and ε4), the presence of the APOE ε4 (E4) allele has been associated with increased risk and earlier onset of Alzheimer's disease (132). It was found that long-chain omega-3 PUFA supplementation did not increase plasma omega-3 concentrations to the same extent in E4 carriers than in non-carriers (133) and that DHA metabolism differs in E4 carriers compared to non-carriers, with greater oxidation and lower plasma concentrations in E4 carriers (134). However, neither APOE genotype nor polymorphisms in 11 other genes associated with Alzheimer's disease were found to modify the inverse relationship between fish intake and risk of cognitive decline in the pooled analysis of the five cohorts (129).

In a recent meta-analysis of observational studies, each one-serving increase of fish intake per week was found to be associated with a 5% lower risk of dementia and a 7% lower risk of Alzheimer's disease (135). Dietary intake level of marine-derived DHA — but not blood DHA concentration — was also inversely associated with the risks of dementia and Alzheimer's disease; for instance, a 100 mg/day increment in dietary DHA intake was associated with lower risks of dementia (-14%) and Alzheimer's disease (-37%) (135). Results from two large cohort studies published after this dose-response meta-analysis showed blood DHA concentration to be positively associated with cognitive performance in adults (136, 137). Findings from preclinical studies suggest that long-chain omega-3 fatty acids may have neuroprotective effects, potentially through mitigating neuroinflammation, improving cerebral blood flow, and/or reducing amyloid aggregation (138).

Randomized controlled trials: A 2012 systematic review identified three randomized controlled trials that examined the effect of omega-3 supplementation on the risk of cognitive decline in cognitively healthy older or elderly adults (139). There was no evidence showing an effect of omega-3 on measures of cognitive functions in these clinical trials. In a more recent systematic review that identified seven trials conducted in cognitively healthy participants, the authors reported positive effects of long-chain omega-3 supplementation on measures of cognitive outcomes in all studies but the second longest and the two largest trials (140). Another seven trials examined the effect of long-chain omega-3 supplementation in individuals with mild cognitive impairment; all but three trials showed a significant benefit on measures of cognitive function or specific memory tasks (140). Yet, two trials that found no improvement in cognitive performance included omega-3 supplements in both intervention and control arms (141, 142).

Overall, the data favor a role for diets rich in long-chain omega-3 fatty acids in slowing cognitive decline, but larger trials with longer intervention periods may be necessary to see a consistent beneficial effect of omega-3 supplementation in older individuals with normal or declining cognitive functions.

Disease Treatment

Hypertriglyceridemia

About one-third of US adults have serum triglycerides >150 mg/dL, and 16% of US adults have serum triglycerides >200 mg/dL (143). The 2011 American Heart Association guidelines on triglyceride management recommended the use of marine-derived omega-3 fatty acid supplements (2-4 g/day of EPA plus DHA) under medical supervision to reduce triglyceride concentrations below 100 mg/dL (143). Hypertriglyceridemia can have various causes, such as inherited and acquired disorders of triglyceride metabolism, poor diet, and/or use of certain medications (143).

Several omega-3 fatty acid preparations have been approved by the US Food and Drug Administration for the treatment of hypertriglyceridemia (104). Out of the five currently available preparations, four contain ethyl esters of EPA and/or DHA and one contains long-chain omega-3 PUFA as free fatty acids (104). The Epanova for lowering very high triglycerides (EVOLVE) randomized controlled trial demonstrated that the omega-3 free fatty acid formulation (2-4 g/day for 12 weeks) effectively reduced triglycerides and other atherogenic factors, including vLDL-cholesterol and remnant-like cholesterol particles, when compared to olive oil (4 g/day) in patients with severe hypertriglyceridemia (serum triglycerides >500 mg/dL) (reviewed in 144). Omega-3 supplementation also decreased inflammation (as shown by a reduction in lipoprotein-associated phospholipase A2) and platelet activation (as shown by a reduction in circulating concentrations of arachidonic acid) (144, 145). This omega-3 formulation also proved to be effective in reducing persistent hypertriglyceridemia (serum triglycerides, 200-499 mg/dL) in patients treated with statins (cholesterol-lowering drugs) (146). Statin use has been found to effectively reduce triglyceride concentrations by about 5%-20% (147). However, a residual elevation in triglycerides and triglyceride-rich lipoprotein cholesterol may remain in a substantial fraction of patients treated with statins. Compared to 4 g/day of olive oil, omega-3 supplementation with 2 or 4 g/day for six weeks reduced triglycerides by 14.6% and 20.6% and non-HDL-cholesterol by 3.9% and 6.9%, respectively (146). The magnitude of these reductions in triglyceride and non-HDL-cholesterol concentrations was similar to what has been observed in other trials that examined the use of ethyl ester omega-3 supplements as add-ons to statin therapy (146, 148-150). A study is underway to assess the benefit of combining omega-3 fatty acids and statins on the risk of major cardiovascular events over a three- to five-year period in patients with hypertriglyceridemia (144, 151).

Nonalcoholic fatty liver disease

Often associated with metabolic disorders, nonalcoholic fatty liver disease (NAFLD) is a condition characterized by an excessive lipid accumulation in the liver (i.e., hepatosteatosis). NAFLD can progress to nonalcoholic steatohepatitis (NASH) in about one-third of the patients with NAFLD, thereby increasing the risk of cirrhosis and hepatocellular carcinoma (152, 153). An emerging feature of NAFLD is the decline in hepatic omega-3 and omega-6 PUFA with disease progression (154). Considering that C_{20-22} omega-3 PUFA can reduce fatty acid synthesis and inflammation, a possible therapeutic strategy would be to increase dietary intake of long-chain omega-3 PUFA. A 2018 meta-analysis of 18 randomized controlled trials in 1,424 participants with NAFLD found that omega-3 supplementation showed beneficial effects on liver fat, specific liver enzymatic activities, serum triglycerides, fasting glucose, and insulin resistance (155). However, there was no evidence of an effect on total cholesterol, LDL-cholesterol, HDL-cholesterol, fasting insulin, blood pressure, BMI, and waist circumference (155). Other recent meta-analyses have also reported that supplementation with long-chain omega-3 fatty acids from fish/seal oil (0.25-6.8 g/day for 3-25 months) improved hepatosteatosis and other metabolic disorders in both children and adults with NAFLD (reviewed in 153). Additional studies are needed to examine their efficacy in more severe cases of NASH.

Inflammatory diseases

Rheumatoid arthritis

A 2017 meta-analysis of 20 randomized controlled trials in 1,252 participants with rheumatoid arthritis assessed the efficacy of long-chain omega-3 PUFA supplementation on a series of clinical outcomes (156). Omega-3 supplementation (0.3-9.6 g/day) for 3 to 18 months reduced the number of tender joints (14 trials), as well as early morning stiffness (15 trials) and pain level (16 trials) compared to placebo. Blood concentrations of triglycerides (3 trials) and pro-inflammatory leukotriene B4 (5 trials) were also decreased with supplemental omega-3 PUFA (156). Another 2017 meta-analysis of 42 randomized controlled trials examined the effect of omega-3 supplementation (mainly as fish oil) on arthritic pain in participants diagnosed with different types of arthritis (157). Daily administration of marine-derived EPA (0.01-4.1 g) and DHA (0.01-2.7 g) for up to 18 months resulted in a reduction in patients' reported pain (using a visual analog scale [VAS] for pain) in those suffering from rheumatoid arthritis (22 trials) and those with other types of arthritis (i.e., juvenile arthritis, psoriatic arthritis) or mixed diagnoses (3 trials), yet not in those with osteoarthritis (5 trials). The evidence of an effect of omega-3 supplements in patients with rheumatoid arthritis was deemed of moderate quality (157). In a 2017 systematic review of 18 trials, including 1,143 subjects with rheumatoid arthritis, only 4 of 18 placebo-controlled trials showed a benefit of omega-3 PUFA supplementation (2.2-3.6 g/day for 12-36 weeks) on pain level — reported by patients and/or assessed by physicians (158). In most trials, the use of medications (nonsteroidal anti-inflammatory drugs [NSAIDs] and/or disease-modifying anti-rheumatic drugs [DMARDs]) was continued throughout the intervention period. Results of a few trials suggested that omega-3 PUFA could spare the need for anti-inflammatory medications in some patients yet failed to show superiority of PUFA in pain management (159, 160).

The limited body of evidence that suggests potential benefits of omega-3 supplementation in rheumatoid arthritis treatment needs strengthening with data from larger studies conducted for longer intervention periods (157, 158).

Inflammatory bowel disease

Crohn's disease: A 2013 systematic review evaluated the efficacy of omega-3 supplementation in patients with Crohn's disease, considering the evidence base from both short-term (9 to 24 weeks) and long-term (1 year) trials (161). Among five trials that evaluated the efficacy of omega-3 supplementation on relapse rates, conflicting outcomes were reported. Most trials were limited by small sample sizes and short duration — up to three years may be necessary to see an effect on relapse rates given the natural relapsing-remitting course of the disease. The two largest and most recent trials (EPIC-1 and EPIC-2) showed no significant effect of omega-3 supplementation on indicators of Crohn's disease remission compared to placebo (162). Other systematic reviews of the literature reached similar conclusions (163-165). Three short-term trials showed positive effects of omega-3 supplementation on plasma biochemical parameters (e.g., reduced inflammatory cytokine expression, increased plasma EPA and DHA concentrations) compared to controls (161). In spite of its impact on biochemical changes in the short-term, however, the ability of omega-3 supplementation to maintain remission or effect clinically meaningful changes in Crohn's disease is not supported by the current evidence (164).

Ulcerative colitis: Seven randomized controlled trials of fish oil supplementation in patients with active ulcerative colitis reported significant improvement in at least one outcome measure, such as decreased corticosteroid use, improved disease activity scores, or improved histology scores (163). In patients with inactive ulcerative colitis, omega-3 supplementation had no effect on relapse rates compared to placebo in four separate trials (163, 165).

While no serious side effects were reported in any trials of fish oil supplementation for the maintenance or remission of inflammatory bowel disease, diarrhea and upper gastrointestinal symptoms occurred more frequently with omega-3 treatment (163-165).

Asthma

Inflammatory eicosanoids (leukotrienes) derived from arachidonic acid (AA; 20:4n-6) are thought to play an important role in the pathology of asthma (32). Because increasing omega-3 fatty acid intake has been found to decrease the formation of AA-derived leukotrienes, a number of clinical trials have examined the effects of long-chain omega-3 fatty acid supplementation on asthma. Although there is some evidence that omega-3 fatty acid supplementation can decrease the production of inflammatory mediators in asthmatic patients (166, 167), evidence that omega-3 fatty acid supplementation decreases the clinical severity of asthma in controlled trials has been inconsistent (168). Three systematic reviews of randomized controlled trials of long-chain omega-3 fatty acid supplementation in asthmatic adults and children found no consistent effects on clinical outcome measures, including pulmonary function tests, asthmatic symptoms, medication use, or bronchial hyperreactivity (169-171).

Immunoglobulin A nephropathy

Immunoglobulin A (IgA) nephropathy is a kidney disorder that results from the deposition of IgA in the glomeruli of the kidneys. The cause of IgA nephropathy is not clear, but progressive renal failure may eventually develop in 15%-40% of patients (172). Since glomerular IgA deposition results in increased production of inflammatory mediators, omega-3 fatty acid supplementation could potentially modulate the inflammatory response and preserve renal function.

A 2012 meta-analysis assessed the efficacy of omega-3 fatty acid supplementation on adult IgA nephropathy (173). Five randomized controlled trials were included in an analysis involving 239 patients (mean age, 37-41 years) who received placebo or supplemental EPA + DHA at doses of 1.4 to 5.1 g/day for 6 to 24 months. Compared with control groups, omega-3 supplementation had no significant effect on urine protein excretion or glomerular filtration rate. Only two trials measured changes in serum creatinine (a marker of renal function) and end-stage renal disease — omega-3 treatment had a beneficial effect on these two parameters in both trials. No adverse events associated with omega-3 supplementation were reported in any of the trials. A more recent review of the literature identified six trials showing evidence of omega-3 supplementation slowing IgA nephropathy disease progression and three trials reporting no effect (174). Additionally, preliminary data suggested that the potential synergistic actions of aspirin and long-chain omega-3 PUFAs might constitute a promising treatment option (168).

Neuropsychiatric disorders

Autism spectrum disorders

Autism spectrum disorders (ASD) refer to three neurodevelopmental disorders of variable severity, namely autism, Asperger syndrome, and pervasive development disorder. ASD are characterized by abnormal information processing in the brain due to alterations in the way nerve cells and their synapses connect and organize. ASD are thought to have a strong genetic basis, yet environmental factors including diet may play an important role. Given that omega-3 and omega-6 PUFA are necessary for neuronal growth and synapse formation (see Biological Activities), they may be of significant benefit in the prevention and/or management of ASD. This is supported by observations of PUFA abnormalities in blood of children with ASD, when compared to their peers with no neurodevelopmental disorders (175). A meta-analysis of case-control studies reported lower blood concentrations of DHA and EPA in children with ASD compared to typically developing children; yet, the ratio of total omega-6 to omega-3 fatty acids was similar between children with and without ASD symptoms (176). A systematic review by the same authors identified six randomized controlled trials that examined the effect of primarily long-chain omega-3 PUFA on ASD symptoms (176). All the studies included children; one study also included adults ≤28 years (177). Four trials used EPA (0.70-0.84 g/day) plus DHA (0.46-0.70 g/day) (178-181), one trial used DHA (0.24 g/day) plus AA (0.24 g/day) (177), and one trial only used only DHA (0.20 g/day) (182). A pooled analysis of four (177-180) of these trials, including a total of 107 participants, showed a small improvement in measures of social interaction and repetitive and restrictive interests and behaviors with long-chain PUFA supplementation for 6 to 16 weeks; however, there was no effect on measures of communication and ASD co-existing conditions, such as hyperactivity, irritability, sensory issues, and gastrointestinal symptoms (176). Two additional systematic reviews and meta-analyses, also published in 2017, identified the same set of trials. One meta-analysis suggested a benefit of long-chain PUFA on measures of lethargy and stereotypy but found no overall clinical improvement compared to placebo (183). The other meta-analysis suggested an improvement regarding lethargy yet a worsening of externalizing behavior and social skills in children supplemented with omega-3 PUFA (184).

The available evidence is based on few trials of small sample sizes and is thus too limited to draw firm conclusions regarding the potential benefit of long-chain PUFA supplementation in ASD management.

Major depression and bipolar disorder

Data from ecologic studies across different countries suggested an inverse association between seafood consumption and national rates of major depression (185) and bipolar disorder (186).

Several small studies have found omega-3 fatty acid concentrations to be lower in plasma (187-189) and adipose tissue (190) of individuals suffering from depression compared to controls. Although it is not known how omega-3 fatty acid intake affects the incidence of depression, modulation of neuronal signaling pathways and eicosanoid production have been proposed as possible mechanisms (191). There may be some benefit of omega-3 PUFA supplementation on depressive disorders, but it is difficult to compare studies and draw conclusions due to great heterogeneity among the trials (192, 193). Small sample sizes, lack of standardization of therapeutic doses, type of omega-3 PUFA administered, co-treatment with pharmacological agents, and diagnostic criteria vary among the trials. A 2012 systematic review of all published randomized controlled trials investigated the effect of omega-3 PUFA supplementation on the prevention and treatment of several types of depression and other neuropsychiatric disorders (192). With respect to major depression, most studies reported a positive effect of omega-3 supplements on depressive symptoms, though efficacy is still considered inconclusive given the great variability among trials. A few themes emerged from this review: more trials reported positive effect for omega-3 PUFA supplements as an adjunct to pharmacological treatment; in monotherapy trials, EPA alone was more effective than DHA alone; and in combination trials, positive effects were more likely if an EPA:DHA ratio of >1.5–2.0 was administered.

A 2014 meta-analysis grouped trials by type of diagnosis of depression (194). A positive effect of omega-3 supplementation was found in 11 trials in participants with a diagnosis of major depressive disorder (according to the Diagnostic and Statistical Manual of Mental Disorders [DSM] criteria). Omega-3 supplementation also appeared to be effective in the pooled analysis of eight trials in participants not formally diagnosed with major depressive disorder, i.e., adults with depressive symptoms despite ongoing treatment, untreated patients with mild-to-severe depressed mood, patients with a history of at least one major depressive episode, women with borderline personality disorder, patients with recurrent self-harm, and postmenopausal women with psychological distress and depressive symptoms. There was no mood improvement with omega-3 supplements in generally healthy adults experiencing depressive symptoms, as suggested by the pooled analysis of six trials (194).

Finally, a 2017 Cochrane systematic review and meta-analysis of 20 randomized controlled trials reported a small benefit of omega-3 supplementation on depressive symptoms when compared to placebo, yet the evidence was deemed of very low quality and the positive effect was judged likely to be biased and not clinically significant (195).

Unipolar depression and bipolar disorder are considered distinct psychiatric conditions, although major depression occurs in both. A 2016 meta-analysis of eight case-control studies that compared the PUFA composition of red blood cell membranes between patients with bipolar disorder and healthy subjects showed abnormally low red blood cell DHA concentrations with bipolar disorder (196). As with major depression, reviews of trials indicated that omega-3 supplementation may have a positive effect as an adjunct to therapy in patients with bipolar disorder (192, 194). Additionally, a 2016 randomized, placebo-controlled trial in 100 participants with bipolar disorder reported a reduction in the severity of manic episodes with daily supplementation of 1,000 mg omega-3 PUFA for three months (197).

While there is some promising evidence for the use of omega-3 fatty acids for major depression and bipolar disorder, additional trials that account for dietary omega-3 intake, changes in red blood cell PUFA concentrations, the ratio of EPA:DHA provided, and co-treatment with medications are necessary.

Schizophrenia

A 2013 meta-analysis of 18 studies compared the PUFA composition of red blood cell membranes in patients with schizophrenia to individuals without the disorder (198). The majority of studies investigated medicated patients, though the authors separated the analysis into three groups of patients at time of measurement in order to account for possible confounding from pharmacologic agents: antipsychotic-medicated, antipsychotic-naïve, and antipsychotic-free. Overall, decreased concentrations of DPA, DHA, and AA in red blood cell membranes were associated with the schizophrenic state. Several mechanisms may account for PUFA abnormalities in schizophrenia, such as altered lipid metabolism, increased oxidative stress, or changes in diet consequent to disease-related behavior.

The use of long-chain omega-3 fatty acid supplements to alleviate symptoms of schizophrenia or to mitigate adverse effects of antipsychotic medications has been investigated in a number of clinical trials (194, 199). In a recent randomized, placebo-controlled trial in 50 subjects with recent onset of schizophrenia who were medicated, daily supplementation with EPA (740 mg) and DHA (400 mg) reduced psychotic symptoms (assessed with the Brief Psychiatric Rating Scale) only in those who were not taking the anxiolytic, lorazepam (Ativan) (200). Overall, however, there was no effect of long-chain PUFA supplements on schizophrenia symptoms. Yet, given the high safety profile of fish oil supplements and some evidence of a positive effect of EPA supplementation in a subset of trials, some clinicians may consider EPA a useful adjunct to antipsychotic therapy in patients with schizophrenia.

Alzheimer's disease and dementia

Several mechanisms suggest that omega-3 PUFA supplementation may improve the cognitive performance of individuals with Alzheimer's disease and other types of dementia. In particular, the antioxidative and anti-inflammatory properties of these PUFA may help protect neurons, promote synaptic plasticity, and limit cellular death. The PUFA composition of the diet appears to influence blood cholesterol, which may play a role in the pathology of Alzheimer's disease. However, the current evidence from clinical trials is not supportive of omega-3 supplementation in the treatment of Alzheimer's disease in humans. A 2016 Cochrane review identified three randomized, placebo-controlled trials in patients with Alzheimer's disease of mild-to-moderate severity (201). These trials compared daily supplementation with DHA (between 675 mg and 1,700 mg) and EPA (between 600 mg and 975 mg) to a placebo for 12 months (202, 203) or 18 months (204). Of note, the study by Quinn et al. (204) also included 4 mg/day of vitamin E (used as preservative — see also Nutrient interactions) in the intervention arm, and the study by Freund-Levi et al. (202) included DHA (900-1,100 mg/day) but no EPA. The pooled analysis of these trials showed no beneficial effect of omega-3 supplementation on measures of global and specific cognitive functions, measures of functional outcomes, and measures of dementia severity (201). There was no difference between intervention and placebo arms regarding the occurrence of adverse effects (201).

Sources

Food sources

Humans can synthesize arachidonic acid (AA) from linoleic acid (LA) and eicosapentaenoic acid (EPA) and docosapentaenoic acid (DHA) from α-linolenic acid (ALA) through a series of desaturation and elongation reactions. EPA and docosapentaenoic acid (DPA) are also obtained from the retroconversion of DHA (see Metabolism and Bioavailability). Due to low conversion efficiency, it is advised to obtain EPA and DHA from additional sources.

Omega-6 fatty acids

Linoleic acid (LA): Food sources of LA include vegetable oils, such as soybean, safflower, and corn oil; nuts; seeds; and some vegetables. Dietary surveys in the US indicate that the average adult intake of LA ranges from 17 to 20 g/day for men and 12 to 13 g/day for women (78). Some foods that are rich in LA are listed in **Table 2**.

Table 2. Food Sources of Linoleic Acid (18:2n-6) (205)

Food	Serving	Linoleic Acid (g)
Safflower oil	1 tablespoon	10.1
Sunflower seeds, oil roasted	1 ounce	9.7
Pine nuts	1 ounce	9.4
Sunflower oil	1 tablespoon	8.9
Corn oil	1 tablespoon	7.3
Soybean oil	1 tablespoon	6.9
Pecans, oil roasted	1 ounce	6.4
Brazil nuts	1 ounce	5.8
Sesame oil	1 tablespoon	5.6

Arachidonic acid: Animals, but not plants, can convert LA to AA. Therefore, AA is absent in vegetable oils and fats and present in small amounts in meat, poultry, and eggs.

Omega-3 fatty acids

α-Linolenic acid (ALA): Flaxseeds, walnuts, and their oils are among the richest dietary sources of ALA. Canola oil is also an excellent source of ALA. Dietary surveys in the US indicate that average adult intakes for ALA range from 1.8 to 2.0 g/day for men and from 1.4 to 1.5 g/day for women (78). Some foods that are rich in ALA are listed in **Table 3**.

Table 3. Food Sources of α-Linolenic Acid (18:3n-3) (205)

Food	Serving	α-Linolenic acid (g)
Flaxseed oil	1 tablespoon	7.3
Chia seeds, dried	1 ounce	5.1
Walnuts, English	1 ounce	2.6
Flaxseeds, ground	1 tablespoon	1.6
Walnut oil	1 tablespoon	1.4
Canola oil	1 tablespoon	1.3
Soybean oil	1 tablespoon	0.9
Mustard oil	1 tablespoon	0.8
Walnuts, black	1 ounce	0.6
Tofu, firm	½ cup	0.2

Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA): Dietary surveys in the US indicate that average adult intakes of EPA range from 0.03 to 0.06 g/day, and average adult intakes of DHA range from 0.05 to 0.10 g/day (78). Oily fish are the major dietary source of EPA and DHA; omega-3 fatty acid-enriched eggs are also available in the US. Some foods that are rich in EPA and DHA are listed in **Table 4**.

Table 4. Food Sources of EPA (20:5n-3) and DHA (22:6n-3) (107)

Food	Serving	EPA (g)	DHA (g)	Amount Providing 1 g of EPA + DHA
Herring, Pacific	3 ounces*	1.06	0.75	1.5 ounces
Salmon, chinook	3 ounces	0.86	0.62	2 ounces
Sardines, Pacific	3 ounces	0.45	0.74	2.5 ounces
Salmon, Atlantic	3 ounces	0.28	0.95	2.5 ounces
Oysters, Pacific	3 ounces	0.75	0.43	2.5 ounces
Salmon, sockeye	3 ounces	0.45	0.60	3 ounces
Trout, rainbow	3 ounces	0.40	0.44	3.5 ounces
Tuna, canned, white	3 ounces	0.20	0.54	4 ounces
Crab, Dungeness	3 ounces	0.24	0.10	9 ounces
Tuna, canned, light	3 ounces	0.04	0.19	12 ounces
*A three-ounce serving of fish is about the size of a deck of cards.				

Supplements

Omega-6 fatty acids

Borage seed oil, evening primrose oil, and black currant seed oil are rich in γ-linolenic acid (GLA; 18:3n-6) and are often marketed as GLA or essential fatty acid (EFA) supplements (206).

Omega-3 fatty acids

Flaxseed oil (also known as flax oil or linseed oil) is available as an ALA supplement. A number of fish oils are marketed as omega-3 fatty acid supplements. The omega-3 fatty acids from natural fish oil are in the triglyceride form, often with only one of three attached fatty acids an omega-3; thus, up to 70% of fatty acids provided may be other types (3). Ethyl esters of EPA and DHA (ethyl-EPA and ethyl-DHA) are concentrated sources of long-chain omega-3 fatty acids that provide more EPA and DHA per gram of oil. Krill oil contains both EPA and DHA and is considered comparable to fish oil as a source of these long-chain PUFA (207). Cod liver oil is also a rich source of EPA and DHA, but some cod liver oil preparations may contain excessive amounts of preformed vitamin A (retinol) and vitamin D (206). DHA supplements derived from algal and fungal sources are also available. Because dietary DHA can be retroconverted to EPA and DPA in humans, DHA supplementation represents yet another alternative to fish oil supplements (see Metabolism and Bioavailability).

The content of EPA and DHA varies in each of these preparations, making it necessary to read product labels in order to determine the EPA and DHA levels provided by a particular supplement. All omega-3 fatty acid supplements are absorbed more efficiently with meals. Dividing one's daily dose into two or three smaller doses throughout the day will decrease the risk of gastrointestinal side effects (see Safety).

Infant formula

In 2001, the FDA began permitting the addition of DHA and AA to infant formula in the United States (208). Presently, manufacturers are not required to list the amounts of DHA and AA added to infant formula on the label. However, most infant formula manufacturers provide this information. The amounts added to formulas in the US range from 8 to 17 mg DHA/100 calories (5 fl oz) and from 16 to 34 mg AA/100 calories. For example, an infant drinking 20 fl oz of DHA-enriched formula daily would receive 32 to 68 mg/day of DHA and 64 to 136 mg/day of AA.

Safety

Adverse effects

γ-Linolenic acid (18:3n-6)

Supplemental γ-linolenic acid is generally well tolerated, and serious adverse side effects have not been observed at doses up to 2.8 g/day for 12 months (209). High doses of borage seed oil, evening primrose oil, or black currant seed oil may cause gastrointestinal upset, loose stools, or diarrhea (206). Because of case reports that supplementation with evening primrose oil induced seizure activity in people with undiagnosed temporal lobe epilepsy (210), people with a history of seizures or a seizure disorder are generally advised to avoid evening primrose oil and other γ-linolenic acid-rich oils (206).

α-Linolenic acid (18:3n-3)

Although flaxseed oil is generally well tolerated, high doses may cause loose stools or diarrhea (211). Allergic and anaphylactic reactions have been reported with flaxseed and flaxseed oil ingestion (212).

Eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3)

Serious adverse reactions have not been reported in those using fish oil or other EPA and DHA supplements. The most common adverse effect of fish oil or EPA and DHA supplements is a fishy aftertaste. Belching and heartburn have also been reported. Additionally, high doses may cause nausea and loose stools.

Potential for excessive bleeding: The potential for high omega-3 fatty acid intakes, especially EPA and DHA, to prolong bleeding times has been well studied and may play a role in the cardioprotective effects of omega-3 fatty acids. Although excessively long bleeding times and increased incidence of hemorrhagic stroke have been observed in Greenland Eskimos with very high intakes of EPA + DHA (6.5 g/day), it is not known whether high intakes of EPA and DHA are the only factor responsible for these observations (1). The US FDA has ruled that intakes up to 3 g/day of long-chain omega-3 fatty acids (EPA and DHA) are Generally Recognized As Safe (GRAS) for inclusion in the diet, and available evidence suggests that intakes less than 3 g/day are unlikely to result in clinically significant bleeding (107). Although the US Institute of Medicine did not establish a tolerable upper intake level (UL) for omega-3 fatty acids, caution was advised with the use of supplemental EPA and DHA, especially in those who are at increased risk of excessive bleeding (see Drug interactions and Nutrient interactions) (1, 206).

Potential for immune system suppression: Although the suppression of inflammatory responses resulting from increased omega-3 fatty acid intakes may benefit individuals with inflammatory or autoimmune diseases, anti-inflammatory doses of omega-3 fatty acids could decrease the potential of the immune system to destroy pathogens (213). Studies comparing measures of immune cell function outside the body (*ex vivo*) at baseline and after supplementing people with omega-3 fatty acids, mainly EPA and DHA, have demonstrated immunosuppressive effects at doses as low as 0.9 g/day for EPA and 0.6 g/day for DHA (1). Although it is not clear if these findings translate to impaired immune responses *in vivo*, caution should be observed when considering omega-3 fatty acid supplementation in individuals with compromised immune systems.

Potential other effects: Although fish oil supplements are unlikely to affect glucose homeostasis, people with diabetes mellitus who are considering fish oil supplements should inform their physician and be monitored if they choose to take them (206).

Infant formula

In early studies of DHA-enriched infant formula, EPA- and DHA-rich fish oil was used as a source of DHA. However, some preterm infants receiving fish oil-enriched formula had decreased plasma AA concentrations, which were associated with decreased weight (but not length and head circumference) (214, 215). This effect was attributed to the potential for high concentrations of EPA to interfere with the synthesis of AA, which is essential for normal growth. Consequently, EPA was removed and AA was added to DHA-enriched formula. Currently available infant formulas in the US contain only AA and DHA derived from algal or fungal sources, rather than fish oil. Randomized controlled trials have not found any adverse effects on growth in infants fed formulas enriched with AA and DHA for up to one year (216).

Pregnancy and lactation

The safety of supplemental omega-3 and omega-6 fatty acids, including borage seed oil, evening primrose oil, black currant seed oil, and flaxseed oil, has not been established in pregnant or lactating (breast-feeding) women (217). Studies of fish oil supplementation during pregnancy and lactation have not reported any serious adverse effects, but use of omega-6/omega-3 PUFA-containing supplements and fish oil supplements in pregnant or nursing women should be monitored by a physician (see Contaminants in fish and Contaminants in supplements) (206).

Contaminants in fish

Some species of fish may contain significant levels of methylmercury, polychlorinated biphenyls (PCBs), or other environmental contaminants (218). In general, larger predatory fish, such as swordfish, tend to contain the highest levels of these contaminants. Removing the skin, fat, and internal organs of the fish prior to cooking and allowing the fat to drain from the fish while it cooks will decrease exposure to a number of fat-soluble pollutants, such as PCBs (219). However, methylmercury is found throughout the muscle of fish, so these cooking precautions will not reduce exposure to methylmercury. Organic mercury compounds are toxic and excessive exposure can cause brain and kidney damage. The developing fetus, infants, and young children are especially vulnerable to the toxic effects of mercury on the brain. In order to limit their exposure to methylmercury, the US Food and Drug Administration (FDA) and Environmental Protection Agency have formulated joint recommendations for women who may become pregnant, pregnant women, breast-feeding women, and parents. These recommendations are presented in **Table 5**.

For more information about the FDA/Environmental Protection Agency advisory for pregnant women and parents of young children on eating fish, see their online brochure. More information about mercury levels in commercial fish and shellfish is available from the FDA.

Of note, the 2015-2020 Dietary Guidelines for Americans recommend the consumption of salmon, anchovies, herring, shad, sardines, Pacific oysters, trout, and Atlantic and Pacific mackerel (not king mackerel), which are higher in EPA and DHA and lower in methylmercury (220).

Contaminants in supplements

Although concerns have been raised regarding the potential for omega-3 fatty acid supplements derived from fish oil to contain methylmercury, PCBs, and dioxins, several independent laboratory analyses in the US have found commercially available omega-3 fatty acid supplements to be free of methylmercury, PCBs, and dioxins (221). The absence of methylmercury in omega-3 fatty acid supplements can be explained by the fact that mercury accumulates in the muscle, rather than the fat of fish (107). In general, fish body oils contain lower concentrations of PCBs and other fat-soluble contaminants than fish liver oils. Additionally, fish oils that have been more highly refined and deodorized contain lower concentrations of PCBs (222). Pyrrolizidine alkaloids, potentially hepatotoxic and carcinogenic compounds, are found in various parts of the borage plant. People who take borage oil supplements should use products that are certified free of unsaturated pyrrolizidine alkaloids (206).

Table 5. Recommendations to Limit Exposure to Seafood Methylmercury (219)

1. Eat 8-12 ounces of a variety of fish a week	• That’s 2 or 3 servings of fish a week • For young children, give them 2 or 3 servings of fish a week with the portion right for the child’s age and calorie needs.
2. Choose fish lower in mercury.	• Many of the most commonly eaten fish are lower in mercury. • Examples include salmon, shrimp, pollock, tuna (light canned), tilapia, catfish, and cod.
3. Avoid 4 types of fish: tilefish from the Gulf of Mexico, shark, swordfish, and king mackerel.	• These 4 types of fish are highest in mercury. • Limit white (albacore) tuna to 6 ounces a week.
4. When eating fish you or others have caught from streams, rivers, and lakes, pay attention to fish advisories on those waterbodies.	• If advice isn’t available, adults should limit such fish to 6 ounces a week and young children to 1 to 3 ounces a week and not eat other fish that week.
5. When adding more fish to your diet, be sure to stay within your calorie needs.	

Drug interactions

γ-Linolenic acid supplements, such as evening primrose oil or borage seed oil, may increase the risk of seizures in people on phenothiazines (neuroleptic agents), such as chlorpromazine (210). High doses of black currant seed oil, borage seed oil, evening primrose oil, flaxseed oil, and fish oil may inhibit platelet aggregation; therefore, these supplements should be used with caution in people on anticoagulant medications (206). In particular, people taking fish oil or long-chain omega-3 fatty acid (EPA and DHA) supplements in combination with anticoagulant drugs, including aspirin, clopidogrel (Plavix), dalteparin (Fragmin), dipyridamole (Persantine), enoxaparin (Lovenox), heparin, ticlopidine (Ticlid), and warfarin (Coumadin), should have their coagulation status monitored using a standardized prothrombin time assay (international normalized ratio [INR]). One small study found that 3 g/day or 6 g/day of fish oil did not affect INR values in 10 patients on warfarin over a four-week period (223). However, a case report described an individual who required a reduction of her warfarin dose when she doubled her fish oil dose from 1 g/day to 2 g/day (224).

Nutrient interactions

Vitamin E

Outside the body, PUFA become rancid (oxidized) more easily than saturated fatty acids. Fat-soluble antioxidants, such as vitamin E (α-tocopherol), play an important role in preventing the oxidation of PUFA. Inside the body, results of animal studies and limited data in humans suggest that the amount of vitamin E required to prevent lipid peroxidation increases with the amount of PUFA consumed (225). One widely used recommendation for vitamin E intake is 0.6 mg of α-tocopherol per gram of dietary PUFA. This recommendation was based on a small study in men and the ratio of α-tocopherol to LA in the US diet and has not been verified in more comprehensive studies. Although EPA and DHA are easily oxidized outside the body, it is presently unclear whether they are more susceptible to oxidative damage within the body (226). High vitamin E intakes have not been found to decrease biomarkers of oxidative damage when EPA and DHA intakes are increased (227, 228), but some experts believe that an increase in PUFA intake, particularly omega-3 PUFA intake, should be accompanied by an increase in vitamin E intake (1).

Intake Recommendations

US Institute of Medicine

The Food and Nutrition Board of the US Institute of Medicine (now the National Academy of Medicine) has established adequate intake (AI) for omega-6 and omega-3 fatty acids (**Tables 6 and 7**) (1).

Table 6. Adequate Intake (AI) for Omega-6 Fatty Acids (1)

Life Stage	Age	Source	Males (g/day)	Females (g/day)
Infants	0-6 months	Omega-6 PUFA*	4.4	4.4
Infants	7-12 months	Omega-6 PUFA*	4.6	4.6
Children	1-3 years	LA#	7	7
Children	4-8 years	LA	10	10
Children	9-13 years	LA	12	10
Adolescents	14-18 years	LA	16	11
Adults	19-50 years	LA	17	12
Adults	51 years and older	LA	14	11
Pregnancy	all ages	LA	-	13
Breast-feeding	all ages	LA	-	13
*The various omega-6 polyunsaturated fatty acids (PUFA) present in human milk can contribute to the AI for infants. # LA, linoleic acid				

Table 7. Adequate Intake (AI) for Omega-3 Fatty Acids (1)

Life Stage	Age	Source	Males (g/day)	Females (g/day)
Infants	0-6 months	ALA, EPA, DHA*	0.5	0.5
Infants	7-12 months	ALA, EPA, DHA	0.5	0.5
Children	1-3 years	ALA	0.7	0.7
Children	4-8 years	ALA	0.9	0.9
Children	9-13 years	ALA	1.2	1.0
Adolescents	14-18 years	ALA	1.6	1.1
Adults	19 years and older	ALA	1.6	1.1
Pregnancy	all ages	ALA	-	1.4
Breast-feeding	all ages	ALA	-	1.3
*All omega-3 polyunsaturated fatty acids present in human milk can contribute to the AI for infants. ALA, α-linolenic acid; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.				

Given the established health benefits of consuming at least two servings of oily fish per week, providing approximately 400 to 500 mg EPA + DHA, some researchers have proposed that the US Institute of Medicine (now the National Academy of Medicine) establish dietary reference intakes (DRIs) for EPA + DHA (27). For now, there are no DRIs for EPA and DHA specifically.

Because maternal dietary intake of long-chain PUFA determines the DHA status of the newborn, several expert panels in the US recommend that pregnant and lactating women consume at least 200 mg DHA per day, close to the amount recommended for adults in general (250 mg/day) (70, 229). The potential benefits associated with obtaining long-chain omega-3 fatty acids through moderate consumption of fish (e.g., 1-2 servings weekly) during pregnancy and lactation outweigh any risks of contaminant exposure, though fish with high concentrations of methylmercury should be avoided (218). For information about contaminants in fish and guidelines for fish consumption by women of childbearing age, see Contaminants in fish.

2015-2020 Dietary Guidelines for Americans

The 2015-2020 Dietary Guidelines provide recommendations for nutritional goals for linoleic acid and α-linolenic acid based on the DRIs (see **Tables 6 and 7**). Seafood, nuts, seeds, and oils, which are all part of healthy dietary patterns, provide essential fatty acids. The 2015-2020 Dietary Guidelines provide dietary recommendations regarding the amounts of these foods for those who choose to follow a healthy US-style eating pattern, a healthy Mediterranean-style eating pattern, or a healthy vegetarian eating pattern (**Table 8**).

Table 8. 2015-2020 Dietary Guidelines for Americans’ Recommendations for Sources of Omega-3 and Omega-6 Polyunsaturated Fatty Acids* (220)

	Healthy Eating Patterns		
Food	US-style	Mediterranean-style	Vegetarian
Seafood (oz-eq/week)	8	15	–
Nuts, seeds, soy products (oz-eq/week)	5	5	7
Oils (g/week)	27	27	27
*Recommendations for total daily energy needs of 2,000 calories per day. Estimates of daily calorie needs according to age, gender, and physical activity can be found in the Appendix 2 of the ‘2015-2020 Dietary Guidelines for Americans’ report (220). Oz-eq, ounce-equivalent			

American Heart Association recommendation

The American Heart Association recommends that people without documented coronary heart disease (CHD) eat a variety of fish (preferably oily) at least twice weekly (230). Two servings of oily fish provide approximately 500 mg of EPA plus DHA. Pregnant women and children should avoid fish that typically have higher levels of methylmercury (see Contaminants in fish). People with documented CHD and those with heart failure without preserved left ventricular function are advised to consume approximately 1 g/day of EPA + DHA preferably from oily fish, or to consider EPA + DHA supplements in consultation with a physician (104, 107). Patients who need to lower serum triglycerides may take 2 to 4 g/day of EPA + DHA supplements under a physician's care (see Hypertriglyceridemia).

International recommendations

Upon request of the European Commission, the European Food Safety Authority (EFSA) proposed adequate intakes (AI) for the essential fatty acids LA and ALA, as well as the long-chain omega-3 fatty acids EPA and DHA (231). EFSA recommends an LA intake of 4% of total energy and an ALA intake of 0.5% of total energy; an AI of 250 mg/day is recommended for EPA plus DHA (232). The European Food and Safety Authority (EFSA) recommends that pregnant and lactating women consume an additional 100 to 200 mg of preformed DHA on top of the 250 mg/day EPA plus DHA recommended for healthy adults (231).

For adults, the World Health Organization recommends an acceptable macronutrient distribution range (AMDR) for omega-6 fatty acid intake of 2.5%-9% of energy and for omega-3 fatty acid intake of 0.5%-2% of energy (233). Their AMDR for EPA plus DHA is 0.25 to 2 g/day (the upper level applying to secondary prevention of coronary heart disease).

The International Society for the Study of Fatty Acids and Lipids (ISSFAL) recommends healthy adults have an LA intake of 2% energy, an ALA intake of 0.7% energy, and a minimum of 500 mg/day of EPA plus DHA for cardiovascular health (234).

Linus Pauling Institute recommendation

The Linus Pauling Institute supports the AI for the essential fatty acids (see Tables 6 and 7) and recommends that generally healthy adults increase their intake of long-chain omega-3 fatty acids by eating fish twice weekly and consuming foods rich in ALA, such as walnuts, flaxseeds, and flaxseed or canola oil. If you don't regularly consume fish, consider taking a two-gram fish oil supplement several times a week. If you are prone to bleeding or take anticoagulant drugs, consult your physician.

Summary

- Dietary fiber is a diverse group of compounds, including lignin and complex carbohydrates, which cannot be digested by human enzymes in the small intestine. *(More information)*
- Although each fiber type is chemically unique, fibers can be classified according to their solubility, viscosity, and fermentability in order to better understand their physiological effects. *(More information)*
- Soluble gel-forming fibers, such as psyllium and fibers found in oat products, can lower serum LDL cholesterol concentrations and normalize blood glucose and insulin responses. *(More information)*

- Improving glycemic control
- Lowering blood pressure
- Improving regularity in stool elimination
- Disease Prevention
  - Cardiovascular disease
  - Type 2 diabetes mellitus
  - Metabolic syndrome
  - Cancer
  - Diarrhea associated with enteral nutrition
  - Fecal incontinence
  - Weight control
  - Mortality

- Intake Recommendations
  - The AI for total fiber
  - Increasing fiber intake
- Authors and Reviewers
- References

- Large/coarse insoluble fibers (e.g., wheat bran) and nonfermentable, soluble gel-forming fibers (e.g., psyllium) can have a potential laxative effect. *(More information)*
- Large prospective cohort studies consistently report inverse associations between consumption of diets rich in fiber and risks of cardiovascular disease and type 2 diabetes mellitus. *(More information)*
- A review of the most recent meta-analyses of observational studies suggests that dietary fiber consumption is inversely associated with the risk of cancer of the esophagus, stomach, colon, pancreas, ovary, and breast. *(More information)*
- Both consumption of fiber-rich diets and supplementation with soluble gel-forming fibers could help improve glycemic control in individuals with type 1 or type 2 diabetes mellitus. *(More information)*
- The Adequate Intake (AI) recommendation for total daily fiber intake is 38 g/day for men and 25 g/day for women. However, the average American consumes only about 17 g/day of dietary fiber, and dietary fiber intake might be closer to 10 g/day in those following a low-carbohydrate diet. *(More information)*
- Some strategies for increasing dietary fiber intake include increasing fruit and nonstarchy vegetable intake, increasing intake of legumes, eating whole-grain cereal or oatmeal for breakfast, substituting whole grains for refined grains, and substituting nuts or popcorn for less healthy snacks. *(More information)*

Introduction

All dietary fibers are resistant to digestion in the small intestine, meaning they arrive intact in the large intestine (1). Although most fibers are carbohydrates, one important factor that determines their susceptibility to digestion by human enzymes is the conformation of the chemical bonds between sugar molecules (glycosidic bonds). Humans lack digestive enzymes capable of hydrolyzing (breaking apart) most β-glycosidic bonds, which explains why amylose, a glucose polymer with α-1,4 glycosidic bonds, is digestible by human enzymes, while cellulose, a glucose polymer with β-1,4 glycosidic bonds, is indigestible (**Figure 1**).

Definitions of Fiber

Although nutritional scientists and clinicians generally agree that a healthy diet should include plenty of fiber-rich foods, agreement on the actual definition of fiber has been more difficult to achieve (2-4). In the 1970s, dietary fiber was defined as remnants of plant cells that are resistant to digestion by human enzymes (5). This definition includes a component of some plant cell walls called lignin, as well as indigestible carbohydrates found in plants. However, this definition omits indigestible carbohydrates derived from animal sources (e.g., chitin) and synthetic (e.g., fructooligosaccharides, polydextrose, wheat dextrin) and carbohydrates that are inaccessible to human digestive enzymes (e.g., resistant starch) (6). These compounds share many of the characteristics of fiber present in plant foods.

Institute of Medicine: dietary, functional, and total fiber

Before establishing intake recommendations for fiber in 2001, a panel of experts convened by the Institute of Medicine (now the National Academy of Medicine) developed definitions of fiber that made a distinction between fiber that occurs naturally in plant foods (dietary fiber) and isolated or synthetic fibers that may be added to foods or used as dietary supplements (functional fiber) (4). However, these distinctions are controversial, and there are other classification systems for dietary fiber (see Other classification systems below).

Dietary fiber

- **Lignin:** Lignin is not a carbohydrate; rather, it is a polyphenolic compound with a complex three-dimensional structure that is found in the cell walls of woody plants and seeds (7).
- **Cellulose:** Cellulose is a glucose polymer with β-1,4 glycosidic bonds found in all plant cell walls (**Figure 1**) (6).
- **β-Glucans:** β-Glucans are glucose polymers with a mixture of β-1,4 glycosidic bonds and β-1,3 glycosidic bonds (**Figure 1**). Oats and barley are particularly rich in β-glucans (7).
- **Hemicelluloses:** Hemicelluloses are a diverse group of polysaccharides (sugar polymers) containing different types of sugar monomers, including glucose, xylose, arabinose, mannose, galactose, rhamnose, or pentose. Glucomannan is a hemicellulose containing about 60% of mannose and 40% of glucose bonded together by β-1,4 glycosidic linkages. Like cellulose, hemicelluloses are found in plant cell walls.
- **Pectins:** Pectins are linear polysaccharides made of 300 to 1,000 monosaccharides, primarily galacturonic acid residues linked together by α-1,4 glycosidic bonds (8). Pectins are soluble viscous fibers that are particularly abundant in berries and other fruit (4).
- **Gums:** Gums are viscous polysaccharides often found in seeds (4). Guar gum extracted from guar beans is a galactomannan polysaccharide composed of mannose and galactose residues. It is used in the food industry for its thickening and stabilizing properties. The viscosity of guar gum is lost when guar gum is partially hydrolyzed to derive partially hydrolyzed guar gum (PHGG).
- **Inulin and oligofructose:** Inulin is a mixture of fructose chains that vary in length and often terminate with a glucose molecule (9). Oligofructose is a mixture of shorter fructose chains that may terminate in glucose or fructose. Inulin and oligofructose occur naturally in plants, such as onions and Jerusalem artichokes.
- **Resistant starch:** Naturally occurring resistant starch is sequestered in plant cell walls and is therefore inaccessible to human digestive enzymes (4). It is fermented by bacteria in the colon. Bananas and legumes are sources of naturally occurring resistant starch. Resistant starch may also be formed by food processing or by cooling and reheating.

Functional fiber

According to the Institute of Medicine's definition, functional fiber "consists of isolated, nondigestible carbohydrates that have beneficial physiological effects in humans" (4). Functional fibers may be nondigestible carbohydrates that have been isolated or extracted from a natural plant or animal source, or they may be manufactured or synthesized. However, designation as a functional fiber by the Institute of Medicine requires the presentation of sufficient evidence of physiological benefit in humans. Fibers identified as potential functional fibers by the Institute of Medicine include:

- Isolated or extracted forms of the dietary fibers listed above.
- **Psyllium:** Psyllium refers to viscous, gel-forming mucilage, which is isolated from the outer coat (husk) of psyllium seeds — known in India as ispaghula husk — from the plant *Plantago ovata* or blond psyllium (4).
- **Chitin and chitosan:** Chitin is a polysaccharide polymer extracted from the exoskeletons of crustaceans, such as crab and lobster. It is a polymer of more than 5,000 acetylated glucosamine units linked by β-1,4 glycosidic bonds. Deacetylated chitin or chitosan thus consists in unbranched chains of glucosamine (8).
- **Fructooligosaccharides:** Fructooligosaccharides are short, synthetic fructose chains terminating with a glucose unit. They are used as food additives (9).
- **Galactooligosaccharides:** Galactooligosaccharides are produced through the enzymatic conversion of lactose and are classified as prebiotics (10).
- **Polydextrose and polyols:** Polydextrose and polyols are synthetic carbohydrates. Polydextrose is made of glucose and sorbitol (a sugar alcohol) and may be used as bulking agent in food. Polyols are non-sugar molecules containing multiple hydroxyl groups (-OH). Polydextrose and polyols are used as sugar substitutes in food (4).
- **Resistant dextrins:** Resistant dextrins, also called resistant maltodextrins, are synthetic indigestible polysaccharides formed when starch is heated and treated with enzymes. They are used as food additives (4).

Total fiber

Total fiber is defined by the Institute of Medicine as "the sum of dietary fiber and functional fiber" (4).

Other classification systems

Fibers can be classified into four clinically meaningful categories according to their physiochemical properties, i.e., their solubility, viscosity, and fermentability (reviewed in 11):

Soluble, viscous/gel forming, readily fermented fibers

E.g., β-glucans from oats and barley, raw guar gum

Soluble fibers dissolve in water, while insoluble fibers do not. Viscous fibers thicken in the presence of water, forming very viscous solutions or even visco-elastic gels. Fermentable fibers are readily metabolized by the gut microbiota (i.e., bacteria that normally colonize the large intestine). Fermentation of fiber results in the formation of short-chain fatty acids (acetate, propionate, and butyrate) and gases (1). Short-chain fatty acids can be absorbed and metabolized to produce energy. Interestingly, the preferred energy source for colonocytes (epithelial cells that line the colon) is butyrate. Fermentation of fiber is estimated to contribute up to 10% of daily energy intake (12). Fibers that are fermentable and can stimulate the growth and/or activity of beneficial gut bacteria are called prebiotic fibers (13). Fibers that are soluble, viscous, and fermentable have been shown to improve glycemic control and to lower blood cholesterol concentration. However, their water-holding capacity is lost when they are fermented in the colon such that they have no laxative effect (see Biological Activities).

Soluble, viscous/gel forming, nonfermented fibers

E.g., psyllium

These fibers can dissolve in water and form viscous gels. They can improve glycemic control and lower blood cholesterol concentration. In addition, they retain their water-holding/gel-forming capacity in the large intestine since they are resistant to fermentation. As a consequence, they can exert a stool-normalizing effect, preventing constipation or softening hard stool as well as firming loose/liquid stool in diarrhea and fecal incontinence (see Biological Activities).

Soluble, nonviscous, readily fermented fibers

E.g., inulin, wheat dextrin, oligosaccharides, resistant starches

Although these fibers can dissolve in water, they cannot provide any health benefits associated with fiber viscosity. They are fully fermented and thus do not exert a laxative effect. They can nonetheless exert a prebiotic effect by influencing the composition of the gut microbiota. *In vitro* studies have shown inulin to selectively stimulate the proliferation of beneficial bacteria and limit the growth of potentially pathogenic bacteria) (see Isolated fibers and supplements) (reviewed in 14). However, no health benefit is currently associated with this fiber-driven prebiotic effect.

Insoluble, poorly fermented fibers

E.g., wheat bran, cellulose, lignin

These fibers do not dissolve in water, do not trap water, and are poorly fermented. Large/coarse fiber particles can have a laxative effect. They can irritate the large intestine mucosa and trigger the secretion of mucus and water, which increases the water content of stools. Small, insoluble fiber particles (e.g., finely ground wheat bran) have no laxative effect and can actually have a constipating effect by adding only to the dry stool mass (see Improving regularity in stool elimination).

Biological Activities

Lowering serum cholesterol

Some, but not all, fibers can improve blood lipid abnormalities observed in conditions like dyslipidemia, overweight/obesity, type 2 diabetes mellitus, and metabolic syndrome. Only supplementation with highly viscous fibers (i.e., gel-forming soluble fibers), such as high molecular weight (MW) β-glucan (found in oat bran), raw guar gum, and psyllium, has been shown to decrease total and LDL-cholesterol concentrations when compared to appropriate controls (e.g., fiber-free supplement, low-fiber supplement, or supplementation with insoluble fiber) (15). A 2009 meta-analysis that combined the results of 21 randomized controlled trials in 1,717 participants with hypercholesterolemia found dose- and time-dependent reductions in total and LDL-cholesterol concentrations with psyllium supplementation (3.0-20.4 g/day for >2 weeks) (16). Additionally, results from two trials showed that, compared to statins alone, combining psyllium and statins resulted in larger reductions in LDL-cholesterol concentrations in individuals with hypercholesterolemia (17). Another more recent meta-analysis of 28 randomized controlled trials examined the cholesterol-lowering effect of psyllium fiber on LDL-cholesterol, non-HDL-cholesterol, and apolipoprotein B (apo B) (18) — non-HDL-cholesterol and apo B appear to better predict cardiovascular events than LDL-cholesterol (19). Supplementation with psyllium at a median dose of 10.2 g/day and for a median of eight weeks to participants with or without hypercholesterolemia reduced LDL-cholesterol by 0.33 mmol/L (28 trials; 1,924 participants), non-HDL-cholesterol by 0.39 mmol/L (27 trials; 1,899 participants), and apo B by 0.05 g/L (9 trials; 895 participants) (18).

Despite considerable heterogeneity across studies, the cholesterol-lowering efficacy of other highly viscous fibers, including β-glucans from oat or barley and glucomannan (a hemicellulose), was also reported in recent meta-analyses of trials conducted by one research team (20-22). The cholesterol-lowering effect of soluble fibers, such as psyllium and β-glucan, is directly linked to their high viscosity. Reduction of the gel-forming capacity of these fibers with pressure and/or heat during processing leads to the loss of their cholesterol lowering capacity (23). Accordingly, low-viscosity soluble fibers (e.g., gum arabic/acacia gum, methylcellulose, low MW β-glucan), nonviscous soluble fermentable fibers (e.g., inulin, fructooligosaccharides, wheat dextrin), and insoluble fibers (e.g., wheat bran) do not decrease serum cholesterol at physiologic levels (15).

Highly viscous fibers can trap bile that is released in the small intestine in response to a meal to assist the digestion and absorption of fatty acids. The main mechanism underlying the cholesterol-lowering effect of these fibers is thus linked to their ability to prevent the reabsorption of bile in the terminal ileum and facilitate its elimination in the stool. In order to maintain sufficient bile for digestion, hepatocytes must increase LDL-cholesterol clearance to synthesize more bile acids as cholesterol is a component of bile (15).

These findings led the FDA to approve health claims in relation to the prevention of heart disease on labels of low cholesterol/saturated fat foods containing ≥0.75 g/serving of β-glucan from whole oat or barley or ≥1.7 g/serving of psyllium (see also Cardiovascular disease) (24).

Improving glycemic control

As with cholesterol lowering, the efficacy of fiber on glycemic control is dependent on viscosity. A 2017 review of 14 randomized controlled trials showed that none of the supplemented soluble, nonviscous, fermentable fibers examined (i.e., inulin, fructooligosaccharide, galactooligosaccharide, and oligofructose) could lead to reductions in postprandial and/or fasting blood glucose concentrations (15). Supplementation with insoluble fiber also failed to improve glycemic control in subjects with elevated fasting blood glucose concentrations (25). In contrast, the capacity of dietary viscous fiber (26, 27) and isolated viscous fibers (28-31) to improve glycemic control has been demonstrated in numerous controlled clinical trials conducted over three decades (15). A 2015 review of the efficacy of psyllium showed evidence of reductions in postprandial blood glucose concentration following a single meal in people with type 2 diabetes mellitus (6 studies) as well as in nondiabetic/euglycemic subjects (11 studies) (32). Supplementation with psyllium also resulted in reductions in postprandial blood insulin concentrations in subjects without type 2 diabetes (6 studies) but not in those with type 2 diabetes (3 studies). Longer-term studies of psyllium supplementation also found reductions in mean fasting glucose (4 studies) and mean glycated hemoglobin (HbA1c; 3 studies) in subjects with type 2 diabetes. Finally, while there was no effect of long-term exposure to psyllium on fasting glucose concentration in healthy individuals with euglycemia (14 studies), the glycemic benefit of psyllium was found to increase proportionally with the increase of baseline fasting glucose concentration (reviewed in 32).

The role of soluble viscous fibers on glycemic control is related to their ability to increase chyme viscosity, thereby slowing the degradation of complex nutrients and allowing the absorption of nutrients, including glucose, along the entire small intestine rather than in the upper small intestine. Absorption of nutrients in the distal ileum has been associated with a reduction in gastric emptying and intestinal transit — through a distal to proximal feedback mechanism — which in turn reduces hunger and food intake (reviewed in 15). Nutrient delivery in the distal ileum also triggers the release of short-lived glucagon-like peptide 1 (GLP-1) into the circulation. GLP-1 improves insulin secretion by pancreatic β-cells in response to glucose absorption and is involved in the regulation of food intake at the central nervous system level (33).

Lowering blood pressure

An analysis of 2004-2014 US National Health and Nutrition Examination Survey (NHANES) data from 18,433 participants found inverse associations between either total, cereal, or vegetable fiber intake and the odds of hypertension (defined according to new 2017 American College of Cardiology/American Heart Association clinical practice guidelines; 34). A 2018 meta-analysis of 22 randomized control trials that examined the effect of isolated soluble fiber supplements or diets enriched with soluble viscous fiber in either normotensive or hypertensive participants found an overall 1.59 mm Hg reduction in systolic blood pressure and 0.39 mm Hg reduction in diastolic blood pressure (35). Further analyses showed that, among all the soluble viscous fiber under examination (β-glucan, guar gum, konjac glucomannan, pectin, and psyllium), only psyllium could reduce systolic blood pressure (mean reduction of 2.39 mm Hg) (35). It is not yet understood how soluble viscous fiber would induce a lowering of blood pressure, but this effect may be indirect and dependent on established benefits of these fiber on other cardiometabolic parameters (see the above sections).

Improving regularity in stool elimination

The benefit of fiber on the regularity with which bulky, soft, easy-to-pass stools are eliminated is best assessed by an increase in stool output and an increase in the water content of stool. There are two mechanisms that support the laxative effects of certain fiber types: (i) large/coarse insoluble fiber (e.g., wheat bran) has an irritating effect on the colonic mucosa, which stimulates the secretion of water and mucus (unlike finely ground wheat bran that has a stool-hardening/constipating effect); and (ii) the presence of soluble viscous, gel-forming fiber (e.g., psyllium) helps stool to resist dehydration in the colon (15). Therefore, only fibers that remain relatively intact during the transit throughout the length of the colon (i.e., that resists bacterial fermentation) and are thus found in the stool can have a potential laxative effect. A 2016 review of fiber interventions conducted by McRorie and Chey (36) examined the potential laxative effect of fermentable fiber; the main findings of this review are summarized in **Table 1**.

Table 1. Interventions Examining the Laxative Effect of Fermentable Fiber (adapted from McRorie and Chey [36])

Fiber	Type of Fiber	Number of Studies	Doses	Laxative Effects	Adverse Effects
β-Glucan, guar gum, xanthan gum	Soluble, viscous, fermentable	5 studies: all conducted in healthy participants; 3 studies with β-glucan and 2 studies (guar gum, xanthan gum)	87-100 g/day (β-glucan) and 15 g/day (guar gum, xanthan gum)	• Stool hardening effect and minimal increase in stool output (β-glucan) • No effect on stool output and stool consistency (guar gum, xanthan gum)	Not reported
Inulin	Soluble, nonviscous, fermentable	11 studies: 3 studies in people with constipation and 8 studies in healthy people	5-20 g/day	• No effect on colonic transit time, stool consistency, stool water content, or stool output	Abdominal pain, bloating, flatulence, and borborygmus (1 study)
Polydextrose	Soluble, nonviscous, fermentable	6 studies: all conducted in healthy participants	8-30 g/day	• No effect on stool output, consistency, bowel movement frequency, or colonic transit time	Flatulence and borborygmus (1 study)
Resistant starch (incl. resistant dextrin)	Soluble, nonviscous, fermentable	6 studies: all conducted in healthy participants	7.5-15 g/day	• Stool hardening effect and reduction in stool output (2 studies) • No effect on consistency, stool water content, stool output, or bowel movement frequency (4 studies)	Not reported

In summary, although the bulk of evidence comes primarily from studies in healthy subjects, supplementation with fermentable fibers appears unlikely to exert a laxative effect in people suffering from constipation (**Table 1**). In contrast, a 2016 meta-analysis of seven randomized controlled trials identified psyllium and nonprebiotics as effectively able to increase stool frequency and improve stool consistency in participants affected by chronic idiopathic constipation (see also Chronic idiopathic constipation) (37) .

Disease Prevention

Observational studies that have identified associations between high-fiber intakes and reductions in chronic disease risk have generally assessed only fiber-rich foods, rather than fiber itself, making it difficult to determine whether the observed benefits are related to fiber or other nutrients and phytochemicals commonly found in fiber-rich foods. In contrast, intervention trials often use isolated fibers to determine whether a specific fiber component has beneficial health effects.

Cardiovascular disease

Prospective cohort studies have consistently reported associations between high intakes of fiber-rich foods and low risks of coronary heart disease (CHD) and total cardiovascular disease (CVD). Three large prospective cohort studies (38-40) found that dietary fiber intakes of approximately 14 g per 1,000 kcal of energy were associated with substantial (16-33%) decreases in the risk of CHD; these results are the basis for the Institute of Medicine's Adequate Intake (AI) recommendation for fiber (see Intake Recommendations) (4). A 2013 meta-analysis of 17 prospective cohort studies found each 7 g/day increase in total dietary fiber intake to be associated with a 9% decrease in risk of coronary or total cardiovascular events (41). The most recent meta-analysis that included 18 prospective studies, with a total of 672,408 participants, found a 7% lower risk of CHD and a 17% lower risk of CHD-related mortality with the highest versus lowest intakes of total dietary fiber (42). Subgroup analyses by type or source of dietary fiber showed evidence of inverse associations between cereal, fruit, or soluble fiber intake and the risk of CHD (42).

The US FDA has approved health claims like the following on the labels of foods containing at least 0.75 g/serving of β-glucan soluble fiber: "Diets low in saturated fat and cholesterol that include at least 3 g/day of β-glucan soluble fiber from either whole oats or barley or a combination of both may reduce the risk of coronary heart disease" (24). Similarly, the FDA has approved health claims on the labels of foods containing at least 1.7 g/serving of psyllium: "Diets low in saturated fat and cholesterol that include at least 7 g/day of soluble fiber from psyllium seed husk may reduce the risk of heart disease" (24).

While the cholesterol-lowering effect of viscous/gel-forming soluble fibers is recognized as a major contributor to the cardioprotective effects of fiber (see Lowering serum cholesterol), other mechanisms are likely to be involved. Findings from pooled analyses of prospective cohort studies found some evidence of an inverse association between the risks of CHD and total CVD and intakes of insoluble fiber (41, 42). In addition, a cross-sectional analysis of 2005-2010 National Health and Nutrition Examination Survey (NHANES) data found dietary fiber intake to be inversely associated with serum LDL-cholesterol concentration, but also with blood pressure, body mass index (BMI), and serum insulin concentration (43). Beneficial effects of fiber-rich diets or isolated fiber consumption on blood glucose and insulin responses and on blood pressure may also likely contribute to observed reductions in CHD risk (see Biological Activities).

Type 2 diabetes mellitus

A 2014 meta-analysis of prospective cohort studies (488,293 participants) found intakes of total fiber (12 studies), cereal fiber (10 studies), fruit fiber (8 studies), and insoluble fiber (3 studies) to be inversely associated with the risk of developing type 2 diabetes mellitus (44). A dose-response data analysis reported a nonlinear relationship between total fiber intake and diabetes risk, with evidence of risk reduction with total fiber intakes ≥25 g/day. A linear dose-response relationship between cereal fiber intake and diabetes risk indicated a 6% reduction in diabetes risk for each 2 g-increment in daily cereal fiber intake. There was no evidence of an inverse association between either vegetable fiber (9 studies) or soluble fiber (3 studies) and the risk of type 2 diabetes (44). Similar findings were reported in another meta-analysis of 18 prospective cohort studies in 617,968 participants (45). Higher versus lower intakes of total fiber were found to be associated with a 15% lower risk of type 2 diabetes (17 studies); the risk of type 2 diabetes was inversely related to the intake of cereal fiber (13 studies) and insoluble fiber (3 studies) but not related to the intake of fruit fiber (11 studies), vegetable fiber (11 studies), or soluble fiber (3 studies) (45). However, only randomized controlled interventions can establish whether there is a link of causality between an exposure (fiber intake) and an outcome (type 2 diabetes). For a discussion of the difference between observational studies and intervention studies, see the article "Epidemiological Studies" in the Spring/Summer LPI 2016 Research Newsletter.

Whole-grain cereals contain insoluble fibers, including cellulose, hemicellulose, and lignin. To date, intervention studies examining the effect of cereal fiber supplementation on the risk of type 2 diabetes are limited (46). In a randomized controlled study of 61 adults with metabolic syndrome, the consumption of a diet based on several whole-grain cereal products for 12 weeks had no effect on fasting plasma concentrations of glucose, insulin, or lipids, or on measures of insulin resistance compared with a refined grain-based diet (47). There was only some weak evidence of an effect of whole-grain cereals on postprandial insulin response (47). A recent 24-month, randomized, double-blind, placebo-controlled trial examined the effect of daily supplementation with 15 g of primarily insoluble fiber on glycemic control in 180 adults with impaired glucose tolerance who were counselled to adopt more healthy lifestyle habits. Insoluble fiber supplementation failed to improve fasting glucose concentration, measures of insulin sensitivity, HbA1c concentration (a marker of glycemic control), as well as glucose and insulin responses after a glucose load compared to placebo (25). Although observational data suggest a protective association of cereal fiber against type 2 diabetes, the current (yet limited) evidence from intervention trials does not support a role for insoluble fiber in glycemic control in individuals at risk of type 2 diabetes.

Fiber-related benefits on glucose homeostasis have been linked to the viscosity of certain soluble fibers (e.g., psyllium, β-glucan, raw guar gum) (see Improving glycemic control). Soluble viscous fibers in cereal, particularly β-glucans, rather than insoluble fiber (and soluble nonviscous fiber), are thus more likely to be involved in a protective effect of cereal intake against type 2 diabetes (48). Apart from fiber, other bioactive compounds in cereal, like magnesium, might contribute to improving glycemic control in people with impaired glucose tolerance (see the article on Magnesium) (49).

The current position of the American Diabetes Association is to encourage people at risk of type 2 diabetes to achieve the daily Adequate Intake (AI) of 14 g/1,000 kcal for dietary fiber (see Intake Recommendations) (50, 51). Adherence to a Mediterranean-style diet, the composition of which intends to meet the AI for fiber, has been associated with a lower risk of developing type 2 diabetes (52, 53).

Metabolic syndrome

Metabolic syndrome is estimated to affect nearly 35% of US adults and half of those older than 60 years (54). The term metabolic syndrome refers to a cluster of metabolic disorders that increase the risk of cardiovascular disease and type 2 diabetes mellitus. The diagnosis in an individual is based on the presence at once of at least three of the following metabolic risk factors: abdominal obesity, dyslipidemia, hypertension, impaired glucose tolerance/insulin resistance, and decreased blood HDL-cholesterol concentration. Two recent meta-analyses of observational studies have reported an inverse association between total fiber intake and odds of metabolic syndrome in cross-sectional studies but not in prospective cohort studies (55, 56).

Cancer

Numerous observational studies have examined the relationship between consumption of fiber and risk of cancer at various sites. A 2014 review compiled published analyses of data from the large, multicenter European Prospective Investigation into Cancer and Nutrition (EPIC) prospective cohort (>500,000 participants). This umbrella review reported evidence of inverse associations between higher versus lower daily total fiber intakes (≥28.5 g/day versus ≤16.4 g/day) and the risk of colorectal, liver, and breast cancers (57). Total fiber intakes were not associated with the risk of cancer at other sites, i.e., the biliary tract, endometrium, prostate, kidney, or bladder. In addition, further analyses suggested that the consumption of cereal fiber was inversely related to the risk of colorectal, stomach, and liver cancers, and vegetable fiber intake was inversely associated with breast cancer. Yet, associations between the consumption of specific fiber types were not examined in relation to the risk of endometrial, kidney, or bladder cancer in EPIC participants (57).

Pooling information from individual observational studies can be helpful to draw conclusions regarding the potential associations between dietary fiber consumption and cancer risk. Results from the most recent meta-analyses of observational studies are reported in **Table 2**.

Table 2. Dietary Fiber Intake and Cancer Risk: Meta-analyses of Observational Studies

Type of Cancer	Type of Observational Studies	Risk Ratio [RR] or Odds Ratio [OR]* (95% Confidence Interval)	Risk Ratio [RR] in Subgroup Analyses (e.g., by fiber type, study type, and cancer subtype)	References
Breast cancer	16 prospective cohort studies	RR: 0.93 (0.89-0.98)	RR: 0.95 (0.86-1.06) in studies reporting on fruit fiber RR: 0.99 (0.92-1.07) in studies reporting on vegetable fiber RR : 0.96 (0.90-1.02) in studies reporting on cereal fiber RR: 0.91 (0.84-0.99) in studies reporting on soluble fiber RR: 0.95 (0.89-1.02) in studies reporting on insoluble fiber	Aune et al. (2015) (93)
*for the highest versus lowest level of fiber intake (unless otherwise specified) **both meta-analyses identified the same 14 observational studies				

Colorectal cancer

Three most recent meta-analyses of observational studies have reported evidence of an inverse association between fiber intake and risk of colorectal cancer (see **Table 2**) (58-60). A recent review that included earlier meta-analyses reached a similar conclusion (61).

Several mechanisms have been proposed to explain why consuming fiber can have a protective effect against colorectal cancer. First, the presence of insoluble, coarse fiber can increase stool bulk thereby promoting the fecal excretion of carcinogens like nitrosamines (62). Fiber can also reduce exposure of the gut mucosa to carcinogens by shortening transit time (62). Secondly, fiber consumption influences the composition of the gut microbiota. *In vitro* studies have shown inulin to selectively stimulate the proliferation of beneficial bacteria while limiting the growth of potentially pathogenic bacteria (reviewed in 14). Gut bacterial imbalance (dysbiosis) has been associated with the incidence of several conditions, including colorectal cancer (63). The major health benefits conferred by the consumption of fiber are thus likely mediated by the bacteria the fiber contributes to feed. Depending on the physicochemical characteristics of fiber, some fiber, like inulin, can be fermented by colonic bacteria and lead to the formation of short-chain fatty acids, namely acetate, propionate, and butyrate. These short-chain fatty acids have been found to protect against gastrointestinal bacterial pathogens (64) and to display anti-inflammatory and anti-carcinogenic actions (65, 66).

A few controlled clinical trials have examined the effect of fiber consumption on the recurrence of colorectal adenomas (precancerous polyps), but none have been conducted in the last two decades. These trials examined the effect of wheat bran fiber (67-71), psyllium (72), and a high-fiber diet (73) on the risk of adenomas in participants with a history of adenomas. A 2017 meta-analysis of these trials found no difference between intervention and control groups in the number of participants with at least one new adenomatous polyp during the follow-up period (2-8 years), regardless of the type of fiber intervention (74).

Breast cancer

A review of four meta-analyses of observational studies reported substantial evidence of an inverse association between dietary fiber intake and breast cancer risk (61). The two most recent meta-analyses of prospective cohort studies found dietary fiber intake to be associated with a 7%-9% lower risk of breast cancer (**Table 2**) (75, 76). Prolonged exposure to estrogens has been associated with an increased risk of breast cancer (77). As mentioned in the previous section, several mechanisms might support the potential protective effect of dietary fiber against cancer, including breast cancer. The results of small, short-term intervention trials in premenopausal and postmenopausal women suggested that a low-fat (10-25% of total energy), high-fiber (25-40 g/day) diet could decrease circulating estrogen concentrations by increasing the excretion of estrogens and by promoting the metabolism of estrogens to less estrogenic forms (78, 79). Estrogens are conjugated in the liver and excreted within the bile into the gastrointestinal lumen; they are then de-conjugated by bacterial β-glucuronidase, re-absorbed as free estrogens through the enterohepatic circulation, and delivered to different organs and tissues like the breast.

Dietary fiber might interfere with estrogen reabsorption by reducing β-glucoronidase activity (80). Alterations in gut bacteria composition have also been reported in women with breast cancer and might contribute to increased estrogen metabolism and absorption, resulting in higher circulating estrogen concentrations (81). However, it is not known whether fiber-associated effects on endogenous estrogen concentrations have a clinically significant impact on breast cancer risk (4). Finally, a healthy microbiota might also promote the degradation of plant-derived molecules other than fiber, such as lignans, which are precursors of metabolites with anti-estrogenic activities (82).

Other cancer sites

A review of the most recent meta-analyses of observational studies suggests that dietary fiber consumption is inversely associated with the risk of cancer of the esophagus (84, 85), stomach (86), pancreas (89, 90), and ovaries (see **Table 2**) (87, 88). The evidence linking fiber intake and esophageal cancer was exclusively based on observations from case-control studies, and for the other cancer sites, the evidence is primarily derived from case-control studies (**Table 2**). It is important to note that the evidence of an inverse association between fiber intake and risk of ovarian cancer (2 meta-analyses) was observed in case-control but not in prospective cohort studies (**Table 2**). Additionally, there was no evidence of an association between fiber intake and risk of endometrial cancer (1 meta-analysis; 83), prostate cancer (2 meta-analyses; 91, 92), or renal cell carcinoma (1 meta-analysis; 93) (**Table 2**). At present, evidence from randomized controlled trials of a causal relationship between fiber intake and risk of any cancer is lacking.

Of note, a recent study in a mouse model presenting a dysbiotic microbiota characterized by an increase in fiber-fermenting bacteria showed that the consumption of an obesogenic, high-fat diet enriched with soluble fiber could cause icteric hepatocarcinoma (94). Such findings suggest that a prolonged consumption of fermentable fiber may have detrimental consequences in contexts of dysbiosis. No such observations were found when insoluble fiber were substituted for soluble fiber (94).

Diarrhea associated with enteral nutrition

Gastrointestinal disorders associated with enteral nutrition prolong the time to recovery. A 2015 meta-analysis of 14 intervention studies found that fiber-enriched enteral formulas and/or fiber supplements reduced the overall incidence of diarrhea in patients requiring enteral nutrition (95). There was no reduction in incidental diarrhea when the analysis was restricted to studies that used prebiotic fiber (i.e., fermentable fiber influencing microbiota composition). Subgroup analyses also showed a benefit of fiber in non-critically ill patients but not in critically ill patients (95).

Fecal incontinence

A prospective cohort study that followed nearly 60,000 older women for four years found that the highest versus lowest level of fiber intake (mean, 25 g/day versus 13.5 g/day) was associated with a 17% lower risk of developing fecal incontinence (defined here as an incontinence episode of liquid or solid stool at least once a month) (96). A limited number of studies have also examined whether fiber supplementation might help treat established fecal incontinence. In one placebo-controlled trial, 206 subjects suffering from fecal incontinence were randomized for 32 days to receive fibers with different degrees of fermentability: gum arabic (on average, 16.6 g/day; highly fermentable), sodium carboxymethylcellulose (16.2 g/day; partially fermentable), and psyllium (14.6 g/day; poorly fermentable) (97). The frequency of fecal incontinence increased with sodium carboxymethylcellulose but decreased with gum arabic and psyllium compared to placebo. Stool consistency and amount did not differ among groups (97). A randomized, cross-over trial in 80 community-dwelling participants with at least one fecal incontinence episode per week found that the reduction in fecal incontinence frequency and severity with psyllium supplementation was equivalent to that observed with antidiarrheal drug loperamide (Imodium) (98).

Weight control

It has been suggested that higher fiber intakes could help maintain weight or promote weight loss by increasing satiation (causing meal termination) and/or extending the feeling of fullness after a meal (satiety). Several mechanisms have been proposed to explain the potential satiating effect of fibers and the subsequent reduction in food intake. The presence of fiber in food may indirectly stimulate the production of hormones involved in the regulation of appetite in particular through (i) increasing the processing time in the mouth due to increased efforts required to masticate large particles containing fibers, and/or (ii) increasing the duration of stomach distention due to a lower rate of gastric emptying, and/or (iii) increasing the colonic production of short-chain fatty acids that can bind to receptors present on gut endocrine cells (reviewed in 99). Adverse effects like gas production and bloating observed with the supplementation of isolated fibers (e.g., wheat dextrin) might also reduce hunger and increase satiety.

A 2013 review of 44 randomized controlled trials found that β-glucans from oat or barley, lupin kernel fiber, whole grain rye, rye bran, and a mixed high-fiber diet could enhance satiety, whereas psyllium, whole grain barley, whole grain buckwheat, resistant starch, and wheat bran had no benefit or even reduced measures of satiety (100). However, for many types of fiber examined, results from interventions were mixed, some showing a positive effect on satiety, and others showing no effect. Additionally, there seemed to be no relationship between the physicochemical properties of fiber (i.e., solubility, viscosity, fermentability) and evidence of efficacy. For example, among soluble viscous fibers, β-glucans appeared to enhance satiety, but pectin or psyllium did not. Similarly, among fermentable fibers, β-glucans enhanced satiety, but guar gum, inulin, fructooligosaccharides, and resistant starch did not. Finally, a positive effect of fiber on satiety was not consistently associated with a reduction in food intake (100).

A 2011 systematic review of 61 randomized controlled studies examined the effect of different fiber types on body weight (101). This analysis found that dextrins and marine polysaccharides reduced body weight in all the studies, while chitosan, arabinoxylans, and fructans reduced body weight in at least two-thirds of the studies. Average weight reductions were greatest for the fructans and marine polysaccharides groups (~1.3 kg or 2.8 lb/4 weeks for a 79 kg person in both groups). For all fiber types combined, however, the average weight reduction was only 0.3 kg (0.7 lb) per 4 weeks for a 79-kg person (101). A few randomized controlled trials in overweight or obese subjects suggested that psyllium supplementation may influence body composition and/or promote weight loss (reviewed in 102). In one randomized, placebo-controlled trial in 159 Australian with body mass indices (BMI) ≥25 kg/m^2, psyllium (5 g/day) reduced waist circumference, waist-to-hip ratio, and body fat percentage, and increased the percentage of lean mass after 3, 6, and 12 months (103). Psyllium appeared to transiently reduce body weight at 3 and 6 months, yet there was no difference in body weight between psyllium and placebo at the end of the intervention (12 months) (103).

More research needs to be conducted in order to clarify which types of fiber might play a role in appetite regulation and weight management (99).

Mortality

Several prospective cohort studies have examined dietary fiber intake in relation to all-cause and cause-specific mortality. A 2015 report from the NIH-AARP Diet and Health Study, which followed 364,442 older adults for an average of 14 years, found that men and women in the highest versus lowest quintile of dietary fiber intake (mean, 10.2 g/day versus 2.0 g/day) had lower risks of all-cause mortality (-19%) and mortality from cardiovascular disease (-20%), cancer (-15%), diabetes mellitus (-34%), and respiratory diseases (-21%) (104). Another prospective study that made use of data collected from 15,740 participants in the US National Health and Nutrition Examination Survey (NHANES) 1988-1994 found a 13% lower risk of all-cause mortality in subjects with total fiber intake between 14.5 g/day and 22.1 g/day — but not in those with higher intake (>22.1 g/day) — compared to those with fiber intake less than 9.3 g/day, over a mean follow-up period of 13.7 years (105). No associations were found between intakes of either insoluble or soluble fiber and all-cause mortality (105).

A meta-analysis of prospective cohort studies published before 2013, which included a total of 1,752,848 participants followed for a mean 12.4 years, found higher versus lower total fiber intake to be associated with lower risks of all-cause mortality (-23%; 9 studies), cancer-related mortality (-17%; 5 studies), and cardiovascular disease-related mortality (-23%; 16 studies) (106). Another meta-analysis identified 14 prospective cohort studies that examined cereal fiber intake in relation to mortality (107). Participants in the highest versus lowest quartile of cereal fiber intake had lower risks of all-cause mortality (-19%; 3 studies), cardiovascular disease-related mortality (-18%; 10 studies), and cancer-related mortality (-25%; 2 studies) (107).

Disease Treatment

Diabetes mellitus

A 2004 meta-analysis that combined the results of 23 clinical trials in patients with type 1 or type 2 diabetes mellitus found that high-fiber diets (≥20 g/1,000 kcal) lowered postprandial blood glucose concentrations by 13%-21%, serum LDL cholesterol concentrations by 8%-16%, and serum triglyceride concentrations by 8%-13% when compared with low-fiber diets (<10 g/1,000 kcal) (108). Based on the evidence from this meta-analysis, the authors recommended a dietary fiber intake of 25-50 g/day (15-25 g/1,000 kcal) for individuals with diabetes, which is slightly higher than recommendations for the general public (14 g/1,000 kcal) (4). However, recommendations from the American Diabetes Association and the Academy of Nutrition and Dietetics to people with diabetes are similar to those prescribed for the population as a whole (50, 109).

Adhering to one of the USDA's healthy dietary patterns, like the Mediterranean-style diet (which is rich in fruit, vegetables, and whole grains), would contribute to meeting the daily intake recommendation for total fiber (see Intake Recommendations) (110). A 2015 meta-analysis of nine randomized controlled trials in a total of 1,178 participants with type 2 diabetes showed evidence of body weight loss and improvements in glycemic control and blood lipid profile with the consumption of a Mediterranean-style diet compared to a control diet (111).

Numerous controlled clinical trials have shown that supplementation with soluble viscous fibers improves markers of glycemic control in people who have type 2 diabetes mellitus. A meta-analysis of 28 trials in 1,394 adults with type 2 diabetes found reductions in HbA1c concentration (20 trials), fasting glucose concentration (28 trials), and insulin resistance (11 trials) with soluble viscous fiber supplementation (median doses of 10.5-15 g/day for 6-8 weeks) (112). Another meta-analysis of 35 trials showed that the effect of psyllium varied with baseline fasting glucose concentration: psyllium supplementation had no effect on markers of glycemic control in euglycemic participants but showed a modest benefit in subjects with impaired glucose tolerance, and a greater effect in those with overt type 2 diabetes (see also Biological Activities) (32).

A small randomized uncontrolled trial in 20 healthy participants suggested that supplemental wheat dextrin, which is partially absorbed as sugar in the small intestine, could increase fasting glucose concentration into the prediabetes range after one month of supplementation (113). Since there is little evidence from clinical trials that increasing nonviscous fiber alone is beneficial (114), individuals with diabetes should preferably increase fiber intake from sources of soluble viscous fibers, such as oats and barley (β-glucans), vegetables, beans, and legumes (108).

Gastrointestinal disorders

Chronic idiopathic constipation

Only insoluble fibers and soluble viscous fibers that resist bacterial fermentation in the colon have a potential laxative effect (see Improving regularity in stool elimination) (15). The prevalence of chronic constipation is higher among people with diabetes mellitus, in women during pregnancy and after delivery, or in older people. The management of constipation in these patients is usually similar to the management in the rest of the population, although the etiology might be different. Bulk-forming laxatives, including psyllium, bran, and methylcellulose, are commonly recommended to improve stool regularity in patients with diabetes mellitus (115). However, there is no evidence that methylcellulose and bran are efficacious in patients with constipation (116). In these patients, psyllium is also recognized to improve glycemic control (see Diabetes mellitus). There is a need for good quality, randomized, double-blind, controlled trials to examine the effect of fiber supplementation in the treatment of constipation in older adults in long-term care (117) or in pregnant women and new mothers (118, 119).

The American College of Gastroenterology recognizes the efficacy of soluble fiber in the treatment of chronic idiopathic constipation. It also recognizes that the evidence from observational studies is mixed, as constipation is associated with low-fiber diets in some, but not all, studies (120). It recommends a gradual increase in fiber intake, in particular to limit the potential adverse effects associated with the intake of insoluble fiber, i.e., bloating, distension, flatulence, and cramping (121).

Irritable bowel syndrome

Irritable bowel syndrome (IBS) is a functional disorder of the intestines, characterized by episodes of abdominal pain or discomfort associated with altered gut mobility and changes in bowel habits (i.e., with constipation, diarrhea, or both) (122). Although the pathophysiology of IBS remains unclear, certain food components have been recognized as a cause for symptoms of IBS. Dietary restriction of highly fermentable, soluble, short-chain carbohydrates, identified as FODMAP (Fermentable Oligosaccharides, Disaccharides, Monosaccharides, and Polyols) and including some dietary fibers (e.g., fructans, galactooligosaccharides), has been found to relieve IBS symptoms, including abdominal pain/discomfort, abdominal bloating/distension, and flatulence (123). On the other hand, soluble, poorly fermentable, long-chain carbohydrate fiber types may improve the symptoms related to excessive gas production. Two meta-analyses of randomized controlled trials and cross-over studies found a beneficial effect of fiber that was limited to soluble fiber, primarily psyllium (124, 125). Accordingly, the American College of Gastroenterology recognizes that soluble fiber like psyllium can provide overall symptom relief in IBS, while insoluble fiber (e.g., wheat bran) can cause bloating and abdominal discomfort (121). More research is needed to document the effect of specific soluble fibers, considering physicochemical properties (viscosity and fermentability), doses, and duration of supplementation, and to provide stronger recommendations to individuals diagnosed with IBS (125). Future trials should also consider subjects with all of the IBS types, i.e., constipation-predominant, diarrhea-predominant, and mixed-diarrhea-and-constipation IBS.

Diverticular disease

Diverticular disease or diverticulosis is a rather common gastrointestinal condition in Western countries characterized by the formation of small pouches (diverticula) in the colon (126). Acute inflammation or infection of diverticula — known as diverticulitis — occurs in about 10%-25% of all symptomatic cases of diverticulosis and is caused by the irritation of the mucosa by fecalith obstructing diverticula. Complications of diverticulitis include abscesses, fistulas, obstruction, and perforation (126). The etiology of diverticulosis is thought to be multifactorial, involving both genetic and environmental risk factors. Despite little supporting evidence, it has been proposed that low fiber intakes that characterize Western diets might contribute to increasing the risk of diverticulosis (127, 128). This low-fiber hypothesis is disputed. In particular, a 2012 cross-sectional study of 2,104 adults found higher odds of diverticula (assessed by colonoscopy) among participants in the highest versus lowest quartile of fiber intake, measured by food frequency questionnaires (129).

A 2017 review identified interventions — published over four decades — that examined the effect of dietary or supplemental fiber on the reduction of abdominal pain in patients suffering from symptomatic uncomplicated diverticular disease (SUDD), as well as on the risk of acute diverticulitis (130). However, a meta-analysis could not be conducted nor any conclusion provided regarding the efficacy of fiber in the treatment of SUDD due to the very poor quality of the studies and their substantial heterogeneity in terms of study design and quantity and quality of fiber types used (130). Another recent review of the literature focused on the effect of fiber-restricted diets in the management of acute uncomplicated diverticulitis (131). Based on the review of three randomized controlled trials and two observational studies, the authors found a reduced length of hospital stay with non-restricted diets compared to restricted diets, but no difference regarding the incidence of treatment failure (i.e., the risk of no clinical improvement with therapy and the development of complications) and the risk of post-discharge reoccurrence of diverticulitis. While there appears to be no clinical benefit in restricting fiber intake in subjects with uncomplicated diverticulitis, the quality of the studies was once again deemed to be very low (131).

Despite the lack of high-quality evidence regarding the potential benefit of fiber in the management of diverticular disease, many national guidelines recommend the use of high-fiber diets in patients with SUDD and for the prevention of diverticulitis (132, 133).

Hemorrhoids

A limited number of interventions have examined the effect of fiber supplementation in subjects with symptomatic hemorrhoids. A randomized controlled trial in 67 participants found that supplementation with psyllium (7 g/day for 6 weeks) improved stool consistency and regularity, reduced the use of laxatives, and increased the quality of life compared to a placebo (134). Another randomized controlled trial in 50 patients with hemorrhoidal prolapse (grades II-IV) and rectal bleeding showed that psyllium supplementation (11.6 g/day for 40 days) reduced the number of bleeding episodes and the number of congested hemorrhoidal cushions but had no effect on the degree of prolapse (135). Finally, a more recent uncontrolled intervention in 102 individuals with advanced hemorrhoids (grades II-IV) examined the effect of counseling patients to follow a therapy meant to improve defecatory habits and involving an increase of psyllium intake to 20 g/day-25 g/day. A follow-up for a median 40 months suggested that psyllium supplementation might help halt the progression of hemorrhoidal prolapse and reduce the number of bleeding episodes (136).

Sources

Food sources

An analysis of the 2009-2010 US National Health and Nutrition Examination Survey (NHANES) data reported average dietary fiber intakes of 13.6 g/day in children and adolescents and 17 g/day in adults—well below recommended intake levels (see Intake Recommendations) (137). Fiber is identified as a shortfall nutrient of public health concern in the 2010-2015 Dietary Guidelines for Americans (51).

Good sources of dietary fiber include legumes, nuts, whole grains, bran products, fruit, and nonstarchy vegetables. Legumes (e.g., dry beans and peas), nuts, seeds, and whole grains are generally more concentrated sources of fiber than fruit and vegetables (138). These higher fiber foods are currently underconsumed, contributing to only about 6% of total dietary fiber intake (137). Although refined grains are often perceived as being poor sources of fiber, they can provide as much fiber as either fruit or vegetables when comparable serving sizes are consumed (138). In addition, not all whole grains are good sources of fiber, yet they provide key micronutrients and phytochemicals that contribute to the health benefit associated with whole grain consumption (see the article on Whole Grains) (12).

All plant-based foods contain a mixture of soluble and insoluble fiber (138). Bran flaxseed, oat cereal, legumes, nuts, fruit, and vegetables are good sources of soluble viscous and nonviscous fiber. Wheat bran, brown rice, barley, cabbage, celery, and whole grains are rich sources of insoluble fiber. The total fiber content of some fiber-rich foods is presented in **Table 3**. Some strategies for increasing dietary fiber intake include increasing fruit and nonstarchy vegetable intake, increasing intake of legumes, eating whole-grain cereal or oatmeal for breakfast, substituting whole grains for refined grains, and substituting nuts or popcorn for less healthy snacks. For more information about the fiber content of specific foods, search USDA's FoodData Central database.

Table 3. Some Food Sources of Dietary Fiber

Food	Serving	Fiber (g)
Legumes		
Navy beans, cooked, boiled	½ cup	9.6
Split peas, cooked, boiled	½ cup	8.1
Lentils, cooked, boiled	½ cup	7.8
Refried beans, canned	½ cup	5.7
Kidney beans, canned	½ cup	5.5
Cereal and grains		
All-bran (wheat) cereal	½ cup	19.5
Oats	½ cup	4.1
Bulgur, cooked	½ cup	4.1
Cereal, instant oatmeal	½ cup	4.0
Pearled barley, cooked	½ cup	3.0
Oat bran, cooked	½ cup	2.8
Quinoa, cooked	½ cup	2.6
Rice, long-grain, brown, cooked	½ cup	1.6
Vegetables		
Winter squash, butternut, cooked, baked	1 cup	6.6
Artichoke hearts, cooked	½ cup	4.8
Spinach, frozen, cooked	½ cup	3.5
Mushrooms, white, cooked from fresh	1 cup	3.4
Brussel sprouts, frozen, cooked	½ cup	3.2
Fruit		
Plums, dried (prunes), uncooked	½ cup, pitted	6.2
Guava, fresh	½ cup	4.5
Pear	1 small pear	4.6
Asian pear	1 small pear	4.4
Raspberries, fresh	½ cup	4.0
Blackberries, fresh	½ cup	3.8
Plums, fresh	2 plums	1.8
Nuts and Seeds		
Almonds	1 ounce (23 kernels)	3.5
Pistachios	1 ounce (49 kernels)	3.0
Pine nuts	1 ounce	3.0
Hazelnuts	1 ounce (21 kernels)	2.7
Pecans	1 ounce (19 halves)	2.7
Peanuts	1 ounce	2.4

Isolated fibers and supplements

β-Glucans

β-Glucans are viscous, easily fermented, soluble fibers found naturally in oats, barley, mushrooms, yeast, bacteria, and algae. β-Glucans extracted from oats, mushrooms, and yeast are available in a variety of nutritional supplements without a prescription.

Glucomannan

Glucomannan, sometimes called konjac mannan, is classified as a soluble fiber isolated from konjac flour, which is derived from the plant *Amorphophallus konjac*. Glucomannan is available as powder and in capsules, which should be taken with plenty of liquids (8). Glucomannan forms gels that are firmer than regular gelatin products (e.g., "jello") and do no melt in the mouth. The FDA has banned gel candies containing glucomannan (e.g., "mini-cup jelly products") because of their potential to cause choking (139).

Pectin

Pectins are readily fermented soluble viscous fibers, most often extracted from citrus peels and apple pulp. Pectins are widely used as gelling agents in food but are also available as dietary supplements without a prescription (8).

Inulins and oligofructose

Inulins and oligofructose, extracted from chicory root or synthesized from sucrose, are used as food additives (9). Isolated inulin is added to replace fat in products like salad dressing, while sweet-tasting oligofructose is added to products like fruit yogurts and desserts. Inulins and oligofructose are highly fermentable fibers that are also classified as prebiotics because of their ability to stimulate the growth of potentially beneficial *Bifidobacteria* species in the human colon (140). Encouraging the growth of *Bifidobacteria* might promote intestinal health by suppressing the growth of pathogenic bacteria known to cause diarrhea or by enhancing the immune response (141). Although a number of dietary supplements containing inulins and oligofructose are marketed as prebiotics, the health benefits of prebiotics have not yet been convincingly demonstrated in humans (11, 142).

Guar gum

Raw guar gum is a viscous, fermentable fiber derived from the Indian guar or cluster bean (4). It is used as a thickener or emulsifier in many food products. Dietary supplements containing guar gum have been marketed as weight-loss aids, but there is no evidence of their efficacy (143). Unlike guar gum, partially hydrolyzed guar gum is nonviscous and therefore does not exhibit the biological activities of guar gum (i.e., it has no effect on serum cholesterol and glycemic control) (see Biological Activities).

Psyllium

Psyllium, a viscous, soluble, gel-forming fiber isolated from psyllium seed husks, is available without a prescription in laxatives, ready-to-eat cereal, and dietary supplements (8). Psyllium is proven to be efficacious to lower serum cholesterol and improve glycemic control (see Biological Activities). Because it also normalizes stool form, psyllium is the only fiber recommended by the American College of Gastroenterology to treat chronic constipation and irritable bowel syndrome (see Gastrointestinal disorders).

Chitosan

Chitosan is an indigestible glucosamine polymer derived from chitin. Chitosan is available as a dietary supplement without a prescription in the US, being marketed to promote weight loss and lower cholesterol. A 2018 meta-analysis of randomized controlled, clinical trials found a lowering of total and LDL-cholesterol concentrations with chitosan supplementation (0.3-6.75 g/day for 4-24 weeks) and no effect on HDL-cholesterol or triglycerides (144). Another recent pooled analysis of trials found chitosan to be more effective than placebo in promoting weight loss (145).

Note: All fiber supplements should be taken with sufficient fluids. Most clinicians recommend taking fiber supplements with at least 8 ounces (240 mL) of water and consuming a total of at least 64 ounces (~2 liters or 2 quarts) of fluid daily (146, 147).

Safety

Adverse effects

Dietary fiber

Some people experience abdominal cramping, bloating, or gas when they abruptly increase their dietary fiber intake (146, 147). These symptoms can be minimized or avoided by increasing intake of fiber-rich foods gradually and increasing fluid intake to at least 64 oz/day (~2 liters or 2 quarts/day). There have been rare reports of intestinal obstruction related to large intakes of oat bran or wheat bran, primarily in people with impaired intestinal motility or difficulty chewing (148-151). The National Academy of Medicine (formerly, the Institute of Medicine) has not established a tolerable upper intake level (UL) for dietary or functional fiber (4).

Isolated fibers and fiber supplements

Gastrointestinal symptoms: The following fibers have been found to cause gastrointestinal distress, including abdominal cramping, bloating, gas, and diarrhea: guar gum, inulin and oligofructose, fructooligosaccharides, polydextrose, resistant starch, and psyllium (4). It is recommended to gradually introduce a new fiber supplement, not exceeding 3 to 4 g/day the first week, in order to minimize gastrointestinal symptoms (152). In subjects who are constipated, the initiation of a fiber supplement should start once the hard stool is cleared (152). Use of a guar gum-containing supplement for weight loss has been associated with esophageal and small bowel obstruction (153). Additionally, several cases of intestinal obstruction by psyllium have been reported when taken with insufficient fluids or by people with impaired swallowing or gastrointestinal motility (154, 155).

Colorectal adenomas: One randomized controlled trial in patients with a history of colorectal adenomas (precancerous polyps) found that supplementation with 3.5 g/day of psyllium for three years resulted in a significant increase in colorectal adenoma recurrence compared to placebo (see Colorectal cancer) (72).

Allergy and anaphylaxis: Since chitin is isolated from the exoskeletons of crustaceans, such as crabs and lobsters, and chitosan is derived from chitin, people with shellfish allergies should avoid taking chitosan supplements (8). Anaphylaxis has been reported after intravenous (IV) administration of inulin (156), as well as ingestion of margarine containing inulin extracted from chicory (157). Anaphylaxis has also been reported after the ingestion of cereal containing psyllium, and asthma has occasionally been reported in people with occupational exposure to psyllium powder (158).

Drug interactions

Gel-forming fibers (e.g., β-glucan, psyllium, raw guar gum, pectin) have the potential to slow the absorption of drugs if taken at the same time. Psyllium may reduce the absorption of lithium, carbamazepine (Tegretol), digoxin (Lanoxin), and warfarin (Coumadin) when taken at the same time (8). Guar gum may slow the absorption of digoxin, acetaminophen (Tylenol), and bumetanide (Bumex) and decrease the absorption of metformin (Glucophage), penicillin, and some formulations of glyburide (Glynase) when taken at the same time (159). Pectin may decrease the absorption of lovastatin (Mevacor) when taken at the same time (160). Concomitant administration of a kaolin-pectin antidiarrheal suspension has been reported to decrease the absorption of clindamycin, tetracycline, and digoxin, but it is not known whether kaolin, pectin, or both were responsible for the interaction (8). In general, medications should be taken at least one hour before or two hours after fiber supplements and gel-forming dietary fibers (e.g., oatmeal).

Nutrient interactions

The addition of cereal fiber to meals has generally been found to decrease the absorption of iron, zinc, calcium, and magnesium in the same meal, but this effect appears to be related to the phytate present in the cereal fiber rather than the fiber itself (161). In general, dietary fiber as part of a balanced diet has not been found to adversely affect the calcium, magnesium, iron, or zinc status of healthy people at recommended intake levels (4). Evidence from animal studies and limited research in humans suggests that inulin and oligofructose may enhance calcium absorption (162, 163). The addition of pectin and guar gum to a meal significantly reduced the absorption of the carotenoids β-carotene, lycopene, and lutein from that meal (164, 165).

Intake Recommendations

The Adequate Intake (AI) for total fiber

The Adequate Intake (AI) recommendations for total fiber intake, set by the Food and Nutrition Board of the Institute of Medicine, are based on the findings of several large prospective cohort studies that dietary fiber intakes of approximately 14 g for every 1,000 calories (kcal) consumed were associated with significant reductions in the risk of coronary heart disease (CHD). The FDA approved specific health claims related to the cardioprotective effects of two soluble, gel-forming fibers only: β-glucan and psyllium (see Disease Prevention). For adults who are 50 years of age and younger, the AI recommendation for total fiber intake is 38 g/day for men and 25 g/day for women. For adults over 50 years of age, the recommendation is 30 g/day for men and 21 g/day for women. The AI recommendations for males and females of all ages are presented in **Table 4** (4).

Table 4. Adequate Intake (AI) for Total Fiber

Life Stage	Age	Males (g/day)	Females (g/day)
Infants	0-6 months	ND*	ND
Infants	7-12 months	ND	ND
Children	1-3 years	19	19
Children	4-8 years	25	25
Children	9-13 years	31	26
Adolescents	14-18 years	38	26
Adults	19-50 years	38	25

Adults	51 years and older	30	21
Pregnancy	all ages	-	28
Breast-feeding	all ages	-	29

Some suggestions for increasing fiber intake

- Eat at least five servings of fruit and vegetables daily (see the article on Fruit and Vegetables).
- Substitute whole grains for refined grains (see the article on Whole Grains).
- Eat oatmeal, whole-grain cereal, or bran cereal for breakfast.
- Eat beans, split peas, or lentils at least once weekly (see the article on Legumes).
- Substitute nuts or popcorn for less healthful snacks like potato chips or candy (see the article on Nuts).

Adopting one of the USDA healthy dietary patterns (i.e., healthy US-style, healthy Mediterranean-style, and healthy vegetarian dietary patterns) recommended in the 2015-2020 Dietary Guidelines for Americans will help meet the recommendations for total fiber intake (110). Fruit, vegetables, and whole grains available in the USDA dietary patterns contribute nearly 90% of the recommended dietary fiber intake. Within the vegetable group, beans, peas, and starchy vegetables are the main contributor of total fiber intake (22%). Refined grains provide 9% of total fiber intake (110).

Dietary Factors

Some of the listed dietary factors (i.e., L-carnitine, coenzyme Q_{10}, and lipoic acid) can be synthesized by the body.

- L-Carnitine
- Coenzyme Q_{10}
- Lipoic Acid
- Phytochemicals
  - Carotenoids
  - Chlorophyll and Chlorophyllin
  - Curcumin
  - Fiber
  - Flavonoids
  - Garlic
  - Indole-3-Carbinol
  - Isothiocyanates
  - Lignans
  - Phytosterols
  - Resveratrol
  - Soy Isoflavones

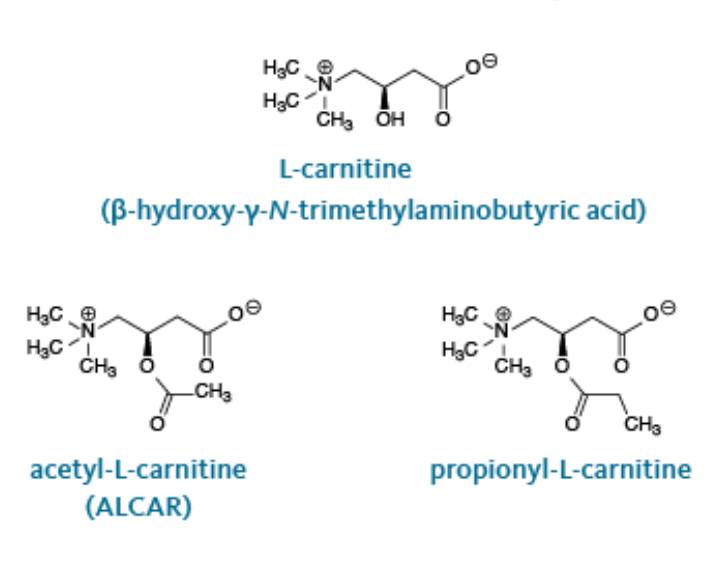
Summary

- Our body produces L-carnitine from the essential amino acid lysine via a specific biosynthetic pathway. Healthy individuals, including strict vegetarians, generally synthesize enough L-carnitine to prevent deficiency. However, certain conditions like pregnancy may result in increased excretion of L-carnitine, potentially increasing the risk for deficiency. *(More information)*
- Because of its role in the transport of long-chain fatty acids from the cytosol to the mitochondrial matrix, L-carnitine is critical for mitochondrial fatty acid β-oxidation. *(More information)*
- L-Carnitine supplementation is indicated for the treatment of primary systemic carnitine deficiency, which is caused by mutations in the gene that codes for the carnitine transporter, OCTN2. *(More information)*
- L-Carnitine is also approved for the treatment of carnitine deficiencies secondary to inherited diseases, such as propionyl-CoA carboxylase deficiency and medium chain acyl-CoA dehydrogenase deficiency, and in patients with end-stage renal disease undergoing hemodialysis. *(More information)*
- Evidence from randomized controlled trials suggests that L-carnitine or acylcarnitine esters may be useful adjuncts to standard medical treatment in individuals with cardiovascular disease. *(More information)*
- Routine administration of L-carnitine to people with end-stage renal disease undergoing hemodialysis is not recommended unless it is to treat carnitine deficiency. *(More information)*
- Acetyl-L-carnitine (ALCAR) may help reduce the severity of chemotherapy-induced peripheral neuropathy. High-quality evidence is needed to evaluate whether ALCAR may benefit the treatment of peripheral neuropathies associated with diabetes or caused by antiretroviral therapy. *(More information)*
- There is some low-quality evidence to suggest that supplemental L-carnitine or ALCAR may be beneficial as adjuncts to standard medical therapy of depression, Alzheimer's disease, and hepatic encephalopathy. *(More information)*
- There is little evidence that L-carnitine supplementation improves cancer-related fatigue, low fertility, or overall physical health. *(More information)*
- If you choose to take L-carnitine supplements, the Linus Pauling Institute recommends acetyl-L-carnitine at a daily dose of 0.5 to 1 g. Note that supplemental L-carnitine (doses, 0.6-7.0 g) is less efficiently absorbed compared to smaller amounts in food. *(More information)*

Introduction

L-Carnitine (β-hydroxy-γ-N-trimethylaminobutyric acid) is a derivative of the amino acid, lysine (**Figure 1**). It was first isolated from meat (*carnus* in Latin) in 1905. Only the L-isomer of carnitine is biologically active (1). L-Carnitine appeared to act as a vitamin in the mealworm (*Tenebrio molitor*) and was therefore termed vitamin B_T (2). Vitamin B_T, however, is a misnomer because humans and other higher organisms can synthesize L-carnitine (see Metabolism and Bioavailability). Under certain conditions, the demand for L-carnitine may exceed an individual's capacity to synthesize it, making it a conditionally essential nutrient (3, 4).

Figure 1. Chemical Structures of L-Carnitine and Two Acylcarnitine Derivatives



[Figure 1 - Click to Enlarge]

Metabolism and Bioavailability

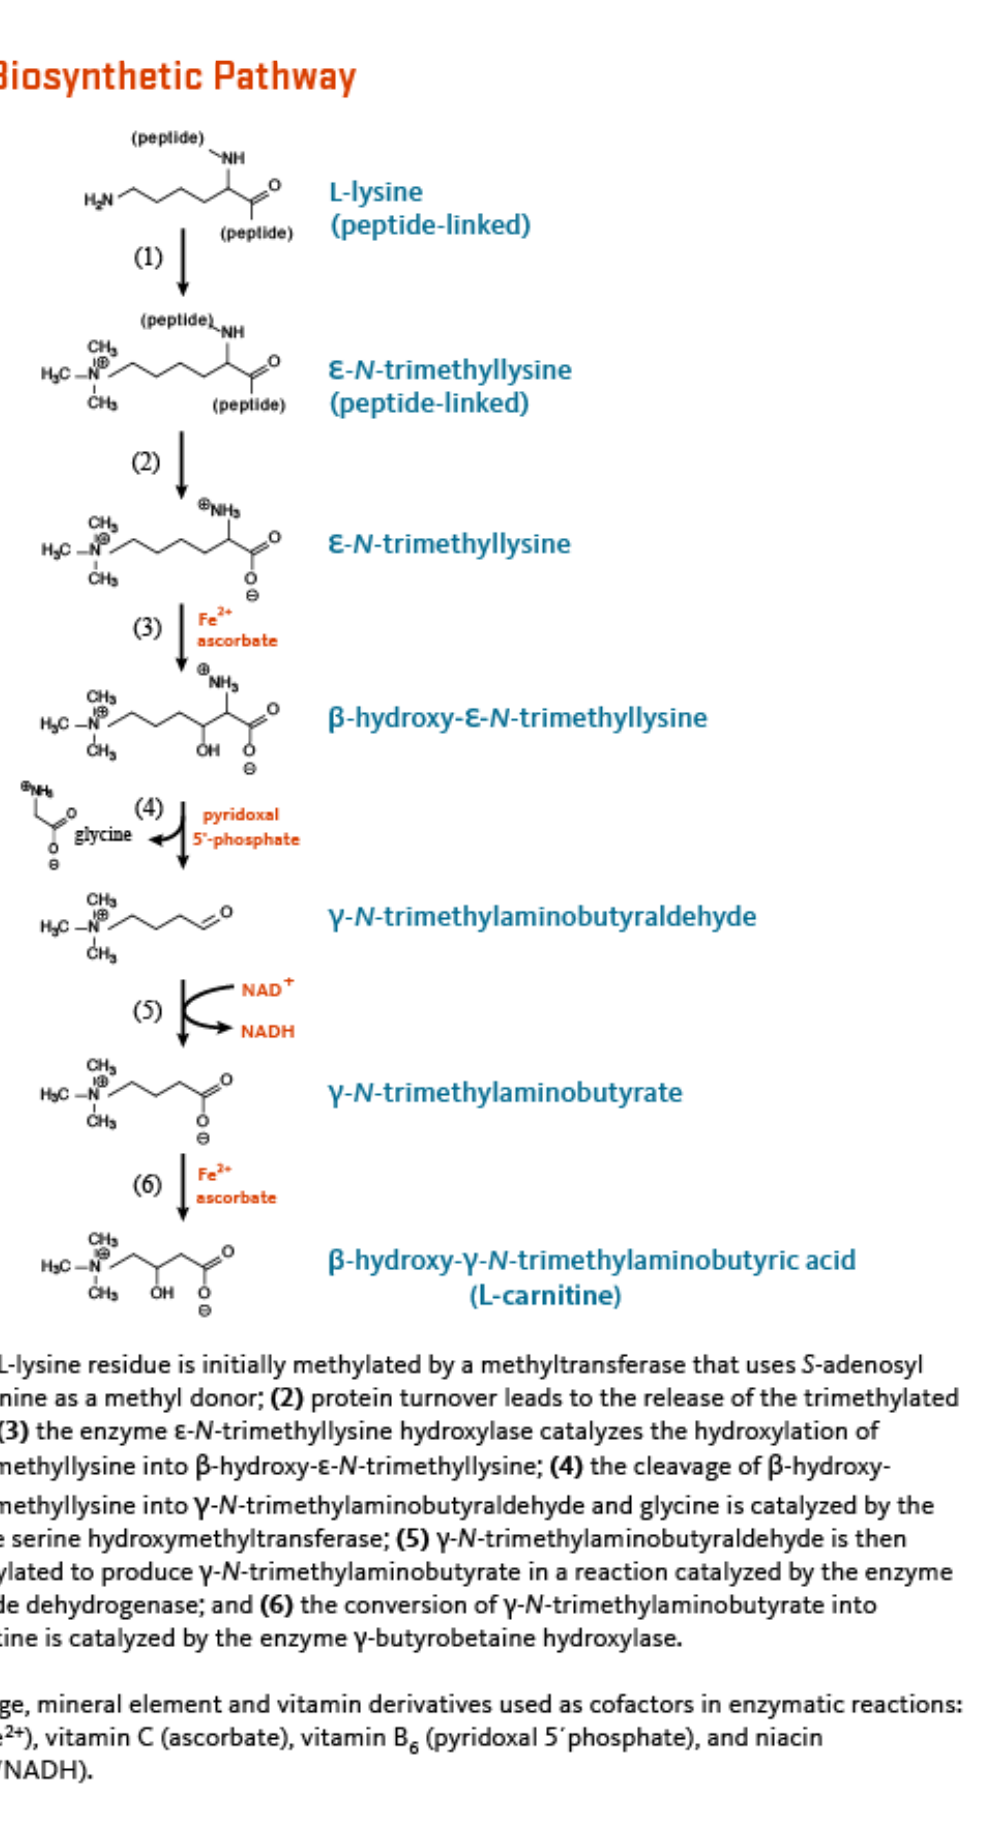
In healthy people, carnitine homeostasis is maintained through endogenous biosynthesis of L-carnitine, absorption of carnitine from dietary sources, and reabsorption of carnitine by the kidneys (5).

Endogenous biosynthesis

Humans can synthesize L-carnitine from the amino acids lysine and methionine in a multi-step process occurring across several cell compartments (cytosol, lysosomes, and mitochondria) (reviewed in 6). Across different organs, protein-bound lysine is methylated to form ε-N-trimethyllysine in a reaction catalyzed by specific lysine methyltransferases that use S-adenosyl-methionine (derived from methionine) as a methyl donor. ε-N-Trimethyllysine is released for carnitine synthesis by protein hydrolysis. Four enzymes are involved in endogenous L-carnitine biosynthesis (**Figure 2**). They are all ubiquitous except γ-butyrobetaine hydroxylase is absent from cardiac and skeletal muscle. This enzyme is, however, highly expressed in human liver, testes, and kidney (7).

L-carnitine is primarily synthesized in the liver and transported via the bloodstream to cardiac and skeletal muscle, which rely on L-carnitine for fatty acid oxidation yet cannot synthesize it (8). The rate of L-carnitine biosynthesis in humans was studied in strict vegetarians (i.e., in people who consume very little dietary carnitine) and estimated to be 1.2 µmol/kg of body weight/day (9). The rate of L-carnitine synthesis depends on the extent to which peptide-linked lysines are methylated and the rate of protein turnover. There is some indirect evidence to suggest that excess lysine in the diet may increase endogenous L-carnitine synthesis; however, changes in dietary carnitine intake level or in renal reabsorption do not appear to affect the rate of endogenous L-carnitine synthesis (6).

Figure 2. Carnitine Biosynthetic Pathway



(1) An L-lysine residue is initially methylated by a methyltransferase that uses *S*-adenosyl methionine as a methyl donor; **(2)** protein turnover leads to the release of the trimethylated lysine; **(3)** the enzyme ε-*N*-trimethyllysine hydroxylase catalyzes the hydroxylation of ε-*N*-trimethyllysine into β-hydroxy-ε-*N*-trimethyllysine; **(4)** the cleavage of β-hydroxy-ε-*N*-trimethyllysine into γ-*N*-trimethylaminobutyraldehyde and glycine is catalyzed by the enzyme serine hydroxymethyltransferase; **(5)** γ-*N*-trimethylaminobutyraldehyde is then hydroxylated to produce γ-*N*-trimethylaminobutyrate in a reaction catalyzed by the enzyme aldehyde dehydrogenase; and **(6)** the conversion of γ-*N*-trimethylaminobutyrate into L-carnitine is catalyzed by the enzyme γ-butyrobetaine hydroxylase.

In orange, mineral element and vitamin derivatives used as cofactors in enzymatic reactions: iron (Fe^{2+}), vitamin C (ascorbate), vitamin B_6 (pyridoxal 5'phosphate), and niacin (NAD^+/NADH).

[Figure 2 - Click to Enlarge]

Absorption of exogenous L-carnitine

Dietary L-carnitine

The bioavailability of L-carnitine from food can vary depending on dietary composition. For instance, one study reported that bioavailability of L-carnitine in individuals adapted to low-carnitine diets (i.e., vegetarians) was higher (66%-86%) than in those adapted to high-carnitine diets (i.e., regular red meat eaters; 54%-72%) (10). The remainder is degraded by colonic bacteria.

L-carnitine supplements

While bioavailability of L-carnitine from the diet is quite high (see Dietary L-carnitine), absorption from oral L-carnitine supplements is considerably lower. The bioavailability of L-carnitine from oral supplements (doses, 0.6 to 7 g) ranges between 5% and 25% of the total dose (5). Less is known regarding the metabolism of the acetylated form of L-carnitine, acetyl-L-carnitine (ALCAR); however, the bioavailability of ALCAR is thought to be higher than that of L-carnitine. The results of *in vitro* experiments suggested that ALCAR might be partially hydrolyzed upon intestinal absorption (11). In humans, administration of 2 g/day of ALCAR for 50 days increased plasma ALCAR concentrations by 43%, suggesting that either ALCAR was absorbed without prior hydrolysis or that L-carnitine was re-acetylated in the enterocytes (5).

Elimination and reabsorption

L-Carnitine and short-chain acylcarnitine derivatives (esters of L-carnitine; see Figure 1) are excreted by the kidneys. Renal reabsorption of free L-carnitine is normally very efficient; in fact, an estimated 95% is thought to be reabsorbed by the kidneys (1). Therefore, carnitine excretion by the kidney is usually very low. However, several conditions can decrease the efficiency of carnitine reabsorption and, correspondingly, increase carnitine excretion. Such conditions include high-fat, low-carbohydrate diets; high-protein diets; pregnancy; and certain disease states (see Primary systemic carnitine deficiency) (12). In addition, when circulating L-carnitine concentration increases, as in the case of oral supplementation, renal reabsorption of L-carnitine may become saturated, resulting in increased urinary excretion of L-carnitine (5). Dietary or supplemental L-carnitine that is not absorbed by enterocytes is degraded by colonic bacteria to form two principal products, trimethylamine and γ-butyrobetaine. γ-Butyrobetaine is eliminated in the feces; trimethylamine is efficiently absorbed and metabolized to trimethylamine-N-oxide, which is excreted in the urine (13).

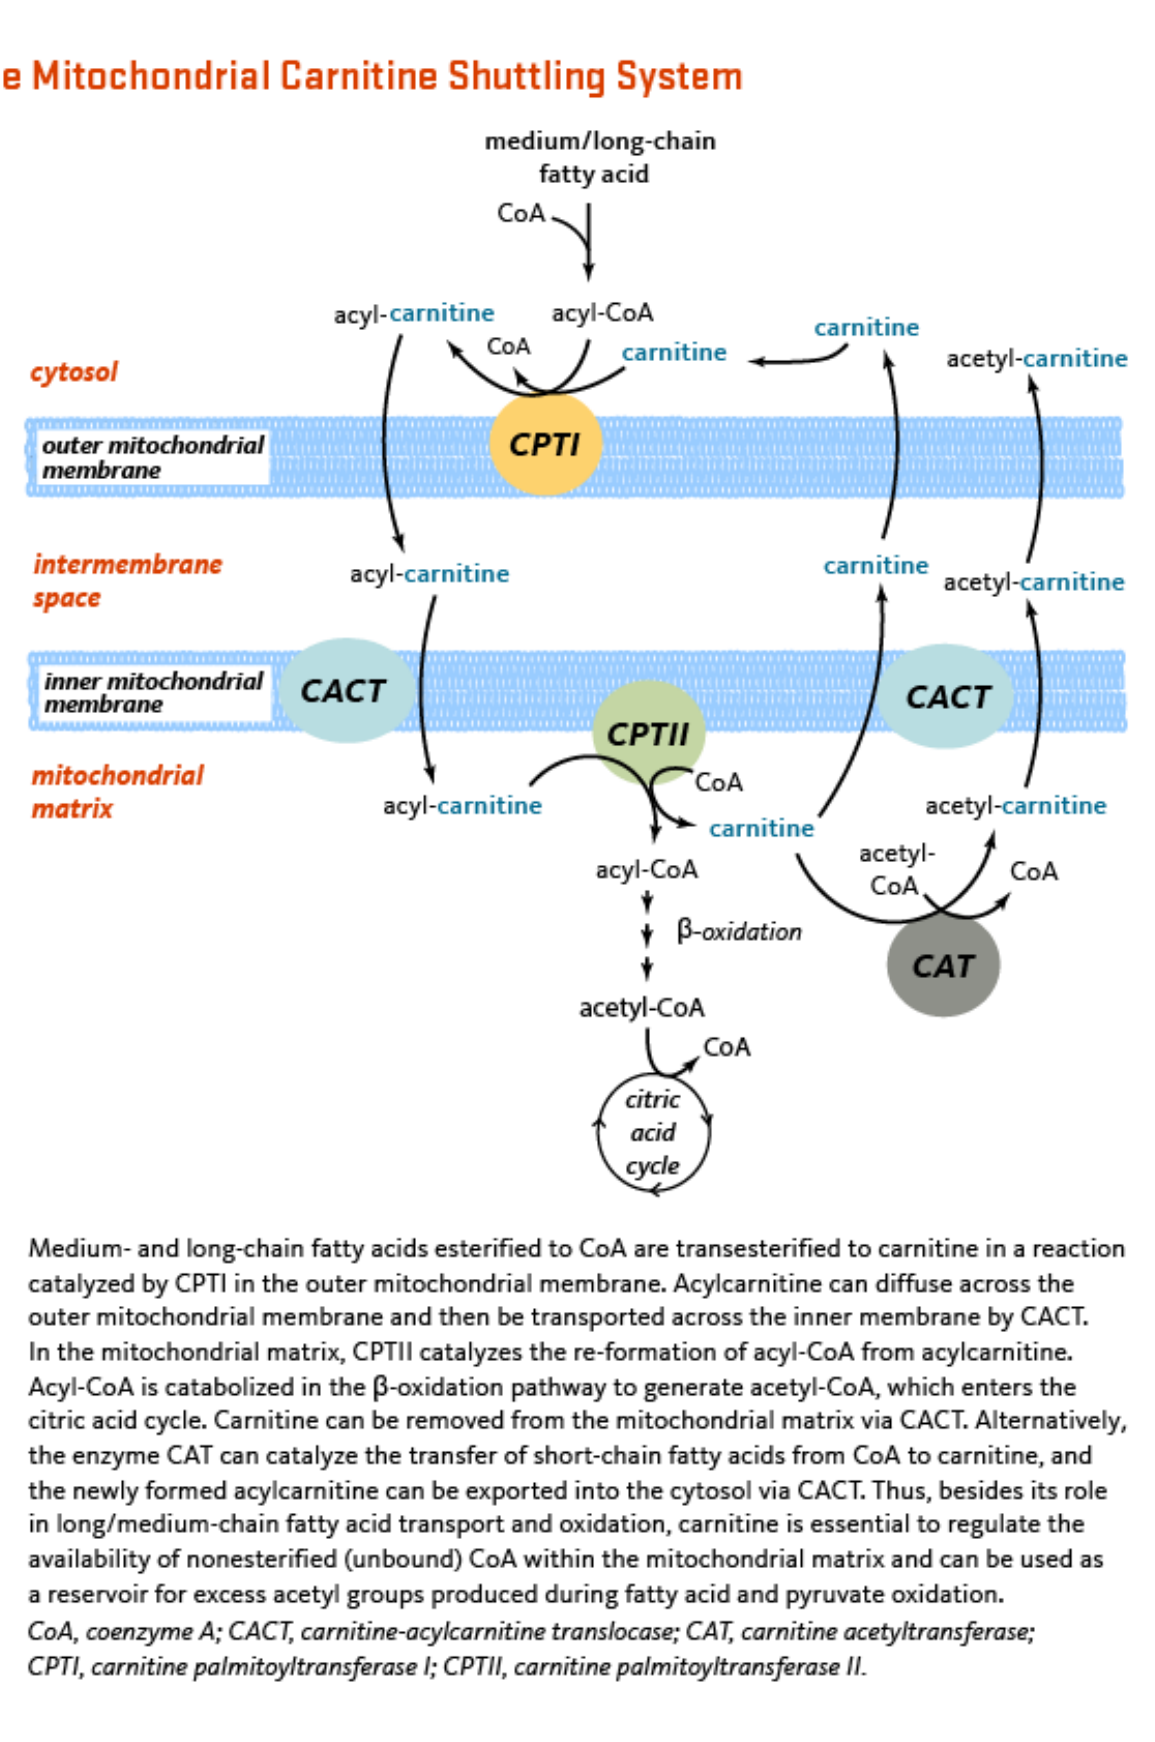
Biological Activities

Mitochondrial oxidation of long-chain fatty acids

L-Carnitine is synthesized primarily in the liver but also in the kidneys and then transported to other tissues. It is most concentrated in tissues that use fatty acids as their primary fuel, such as skeletal and cardiac muscle. In this regard, L-carnitine plays an important role in energy production by conjugating to fatty acids for transport from the cytosol into the mitochondria (6).

L-Carnitine is required for mitochondrial β-oxidation of long-chain fatty acids for energy production (1). Long-chain fatty acids must be esterified to L-carnitine (acylcarnitine) in order to enter the mitochondrial matrix where β-oxidation occurs (**Figure 3**). On the outer mitochondrial membrane, CPTI (carnitine-palmitoyl transferase I) catalyzes the transfer of medium/long-chain fatty acids esterified to coenzyme A (CoA) to L-carnitine. This reaction is a rate-controlling step for the β-oxidation of fatty acid (13). A transport protein called CACT (carnitine-acylcarnitine translocase) facilitates the transport of acylcarnitine across the inner mitochondrial membrane. On the inner mitochondrial membrane, CPTII (carnitine-palmitoyl transferase II) catalyzes the transfer of fatty acids from L-carnitine to free CoA. Fatty acyl-CoA is then metabolized through β-oxidation in the mitochondrial matrix, ultimately yielding propionyl-CoA and acetyl-CoA (6). Carnitine is eventually recycled back to the cytosol (**Figure 3**).

Figure 3. The Mitochondrial Carnitine Shuttling System



Medium- and long-chain fatty acids esterified to CoA are transesterified to carnitine in a reaction catalyzed by CPTI in the outer mitochondrial membrane. Acylcarnitine can diffuse across the outer mitochondrial membrane and then be transported across the inner membrane by CACT. In the mitochondrial matrix, CPTII catalyzes the re-formation of acyl-CoA from acylcarnitine. Acyl-CoA is catabolized in the β-oxidation pathway to generate acetyl-CoA, which enters the citric acid cycle. Carnitine can be removed from the mitochondrial matrix via CACT. Alternatively, the enzyme CAT can catalyze the transfer of short-chain fatty acids from CoA to carnitine, and the newly formed acylcarnitine can be exported into the cytosol via CACT. Thus, besides its role in long/medium-chain fatty acid transport and oxidation, carnitine is essential to regulate the availability of nonesterified (unbound) CoA within the mitochondrial matrix and can be used as a reservoir for excess acetyl groups produced during fatty acid and pyruvate oxidation.
CoA, coenzyme A; CACT, carnitine-acylcarnitine translocase; CAT, carnitine acetyltransferase; CPTI, carnitine palmitoyltransferase I; CPTII, carnitine palmitoyltransferase II.

[Figure 3 - Click to Enlarge]

Regulation of energy metabolism through modulation of acyl CoA:CoA ratio

Free (nonesterified) CoA is required as a cofactor for numerous cellular reactions. The flux through pathways that require nonesterified CoA, such as the oxidation of glucose, may be reduced if all the CoA available in a given cell compartment is esterified. Carnitine can increase the availability of nonesterified CoA for these other metabolic pathways (6). Within the mitochondrial matrix, CAT (carnitine acetyl transferase) catalyzes the transesterification of short- and medium-chain fatty acids from CoA to carnitine (**Figure 3**). The resulting acylcarnitine esters (e.g., acetylcarnitine) can remain in the mitochondrial matrix or be exported back into the cytosol via CACT. Free (nonesterified) CoA can then participate in other reactions, such as the generation of acetyl-CoA from pyruvate in a reaction catalyzed by pyruvate dehydrogenase (14). Acetyl-CoA can then be oxidized to produce energy (ATP) in the citric acid cycle.

Other functions in cellular metabolism

In addition to its importance for energy production, L-carnitine was shown to display direct antioxidant properties *in vitro* (15). Age-related declines in mitochondrial function and increases in mitochondrial oxidant production are thought to be important contributors to the adverse effects of aging. Tissue L-carnitine concentrations have been found to decline with age in humans and animals (16). The expression of most proteins involved in the transport of carnitine (OCTN2) and the acylcarnitine shuttling system across the mitochondrial membrane (CPTIa, CPTII, and CAT; **Figure 3**) was also found to be much lower in the white blood cells of healthy older adults than of younger adults (17).

Preclinical studies in rodents showed that supplementation with high doses of acetyl-L-carnitine (ALCAR; **Figure 1**) reversed a number of age-related changes in liver mitochondrial function yet increased liver mitochondrial oxidant production (18). ALCAR supplementation in rats has also been found to improve or reverse age-related mitochondrial declines in skeletal and cardiac muscular function (19, 20). Co-supplementation of aged rats with L-carnitine and α-lipoic acid blunted age-related increases in reactive oxygen species (ROS), lipid peroxidation, protein carbonylation, and DNA strand breaks in a variety of tissues (heart, skeletal muscle, and brain) (21-30). Co-supplementation for three months improved both the number of total and intact mitochondria and mitochondrial ultrastructure of neurons in the hippocampus (30). Although ALCAR exerts antioxidant activities in rodents, it is not known whether taking high doses of ALCAR will have similar effects in humans.

Deficiency

Nutritional carnitine deficiencies have not been identified in healthy people without metabolic disorders, suggesting that most people can synthesize enough L-carnitine (1). Even strict vegetarians (vegans) show no signs of carnitine deficiency, despite the fact that most dietary carnitine is derived from animal sources (9). Infants, particularly premature infants, are born with low stores of L-carnitine, which could put them at risk of deficiency given their rapid rate of growth. One study reported that infants fed carnitine-free, soy-based formulas grew normally and showed no signs of a clinically relevant carnitine deficiency; however, some biochemical measures related to lipid metabolism differed significantly from infants fed the same formula supplemented with L-carnitine (31). Soy-based infant formulas are now fortified with the amount of L-carnitine normally found in human milk (32).

Carnitine status

Renal filtration maintains plasma concentrations of free carnitine around 40 to 50 micromoles (µmol)/L, while plasma concentrations of acetyl-L-carnitine (ALCAR; the most abundant carnitine ester) are around 3 to 6 µmol/L (8). Regardless of the etiology, plasma concentrations of free carnitine ≤20 µmol/L and increased acylcarnitine/free carnitine ratios (≥0.4) are considered abnormal (6). Low carnitine status is generally due to impaired mitochondrial energy metabolism or to carnitine not being efficiently reabsorbed by the kidneys. The rate of carnitine excretion is not a useful indicator of carnitine status because it can vary with dietary carnitine intake and other physiologic parameters. At present, there is no test that assesses functional carnitine deficiency in humans (6).

Primary systemic carnitine deficiency

Primary systemic carnitine deficiency is a rare, autosomal recessive disorder caused by mutations (including deletions) in the *SLC22A5* gene coding for carnitine transporter protein OCTN2 (organic cation transporter novel 2) (33). Individuals with defective carnitine transport have poor intestinal absorption of dietary L-carnitine, impaired L-carnitine reabsorption by the kidneys (i.e., increased urinary loss of L-carnitine), and defective L-carnitine uptake by muscles (4). The clinical presentation can vary widely depending on the type of mutation affecting *SLC22A5* and the phenotypic manifestation of the mutation, i.e., age of onset, organ involvement, and severity of symptoms at the time of diagnosis (34). The disorder usually presents in early childhood and is characterized by episodes of hypoketotic hypoglycemia (that can cause encephalopathy), hepatomegaly, elevated liver enzymes (transaminases), and hypoammonemia in infants; progressive cardiomyopathy, elevated creatine kinase, and skeletal myopathy in childhood; or fatigability in adulthood (34, 35). The metabolic and myopathic symptoms in infants and children can be fatal such that treatment should start promptly to prevent irreversible organ damage (34). The diagnosis is established by demonstrating abnormally low plasma free carnitine concentrations, reduced carnitine transport of fibroblasts from skin biopsy, and molecular analysis of the gene coding for OCTN2 (33, 34). Treatment consists of pharmacological doses of L-carnitine that are meant to maintain a normal blood carnitine concentration, thereby preventing the risk of hypoglycemia and correcting metabolic and myopathic manifestations (34).

Secondary carnitine deficiency or depletion

Secondary carnitine deficiency or depletion may result from either genetic or acquired conditions.

Hereditary causes include genetic defects in the metabolism of amino acids, cholesterol, and fatty acids, such as propionyl-CoA carboxylase deficiency (aka propionic acidemia) and medium chain acyl-CoA dehydrogenase deficiency (36). Such inherited disorders lead to a buildup of organic acids, which are subsequently removed from the body via urinary excretion of acylcarnitine esters. Increased urinary losses of carnitine can lead to the systemic depletion of carnitine (6).

Systemic carnitine depletion can also occur in disorders of impaired renal reabsorption. For instance, Fanconi's syndrome is a hereditary or acquired condition in which the proximal tubular reabsorption function of the kidneys is impaired (37). This malfunction consequently results in increased urinary losses of carnitine. Patients with renal disease who undergo hemodialysis are at risk for secondary carnitine deficiency because hemodialysis removes carnitine from the blood (see End-stage renal disease) (38).

One example of an exclusively acquired carnitine deficiency involves chronic use of pivalate-conjugated antibiotics. Pivalate is a branched-chain fatty acid anion that is metabolized to form an acyl-CoA ester, which is transesterified to carnitine and subsequently excreted in the urine as pivaloyl carnitine. Urinary losses of carnitine via this route can be 10-fold greater than the sum of daily carnitine intake and biosynthesis and lead to systemic carnitine depletion (see Drug interactions) (39).

Finally, a number of inherited mutations in genes involved in carnitine shuttling and fatty acid oxidation pathways do not systematically result in carnitine depletion (such that carnitine supplementation may not help mitigate the symptoms) but lead to abnormal profiles of acylcarnitine esters in blood (35, 40).

Nutrient interactions

Endogenous biosynthesis of L-carnitine is catalyzed by the concerted action of four different enzymes (see Metabolism and Bioavailability) (**Figure 2**). This process requires two essential amino acids (lysine and methionine), iron (Fe^{2+}), vitamin B_6 in the form of pyridoxal 5'-phosphate, niacin in the form of nicotinamide adenine dinucleotide (NAD), and may also require vitamin C (ascorbate) (4). One of the earliest symptoms of vitamin C deficiency is fatigue, thought to be related to decreased synthesis of L-carnitine (41).

Disease Treatment

In most studies discussed below, it is important to note that treatment with L-carnitine or acyl-L-carnitine esters (i.e., acetyl-L-carnitine [ALCAR], propionyl-L-carnitine; **Figure 1**) was generally used as an adjunct to standard medical therapy, not in place of it. It is also important to consider the fact that the bioavailability of L-carnitine and acylcarnitine derivatives administered orally is low (~10-20%) (see Metabolism and Bioavailability). Intravenous administration is more likely to increase plasma carnitine concentration, yet homeostatic mechanisms tightly control blood concentration through metabolism and renal excretion: Up to 90% of 2 g of L-carnitine administered intravenously is excreted into the urine within 12 to 24 hours. Only a fraction of the dose is thought to enter the endogenous carnitine pool — largely found in skeletal muscle (reviewed in 8).

Type 2 diabetes mellitus

Several small clinical trials have explored whether supplemental L-carnitine could improve glucose tolerance in people with impaired glucose metabolism. A potential benefit of L-carnitine in these patients is based on the fact that it can (i) increase the oxidation of long-chain fatty acids which accumulation may contribute to insulin resistance in skeletal muscle, and (ii) enhance glucose utilization by reducing acyl-CoA concentration within the mitochondrial matrix (see Biological Activities) (42). A meta-analysis of five trials in participants with either impaired fasting glucose, type 2 diabetes mellitus, or nonalcoholic steatohepatitis found evidence of an improvement in insulin resistance with supplemental L-carnitine compared to placebo (43). Another meta-analysis of four randomized, placebo-controlled trials found evidence of a reduction in fasting plasma glucose concentration and no improvement of glycated hemoglobin concentration in subjects with type 2 diabetes mellitus supplemented with acetyl-L-carnitine (ALCAR) (44). A third meta-analysis of 16 trials suggested that supplementation with (acyl)-L-carnitine may reduce fasting blood glucose and glycated hemoglobin concentrations, but not resistance to insulin (45). In a recent double-blind, randomized, placebo-controlled trial, the effect of ALCAR was examined in 229 participants treated for type 2 diabetes mellitus, hypertension, and dyslipidemia (46). ALCAR supplementation (1 g/day for 6 months) had no effect on systolic or diastolic blood pressure, markers of kidney function (i.e., glomerular filtration rate and albuminuria), markers of glucose homeostasis (i.e., glucose disposal rate, glycated hemoglobin concentration, and a measure of insulin resistance), and blood lipid profile (i.e., concentrations of triglycerides, lipoprotein (a), LDL-cholesterol, HDL-cholesterol, and total cholesterol) (46).

Cardiovascular disease

In the studies discussed below it is important to note that treatment with L-carnitine or propionyl-L-carnitine was used as an adjunct (in addition) to appropriate medical therapy, not in place of it.

Myocardial infarction

Myocardial infarction (MI) occurs when an atherosclerotic plaque in a coronary artery ruptures and obstructs the blood supply to the heart muscle, causing injury or damage to the heart (see the page on Heart Attack). Several clinical trials have explored whether L-carnitine administration immediately after MI diagnosis could reduce injury to heart muscle resulting from ischemia and improve clinical outcomes. An early trial in 160 men and women diagnosed with a recent MI showed that oral L-carnitine (4 g/day) in addition to standard pharmacological treatment for one year significantly reduced mortality and the occurrence of angina attacks compared to the control (47). In another controlled trial in 96 patients, treatment with intravenous L-carnitine (5 g bolus followed by 10 g/day for three days) following a MI resulted in lower concentrations of creatine kinase-MB and troponin-I, two markers of cardiac injury (48). However, not all clinical trials have found L-carnitine supplementation to be beneficial after MI. For example, in a randomized, double-blind, placebo-controlled trial in 60 participants diagnosed with an acute MI, neither mortality nor echocardiographic measures of cardiac function differed between patients treated with intravenous L-carnitine (6 g/day) for seven days followed by oral L-carnitine (3 g/day) for three months and those given a placebo (49). Another randomized placebo-controlled trial in 2,330 patients with acute MI, L-carnitine therapy (9 g/day intravenously for five days, then 4 g/day orally for six months) did not affect the risk of heart failure and death six months after MI (50).

A 2013 meta-analysis of randomized controlled trials found that L-carnitine therapy in patients who experienced an MI reduced the risks of all-cause mortality (-27%; 11 trials; 3,579 participants), ventricular arrhythmias (-65%; five trials; 229 participants), and angina attacks (-40%; 2 trials; 261 participants), but had no effect on the risks of having a subsequent myocardial infarction or developing heart failure (51). Because about 90% of oral L-carnitine supplements is unlikely to be absorbed, one could ask whether the efficacy is equivalent between protocols using both intravenous and oral administration and those using oral administration only (8). This has not been examined in subgroup analyses.

Heart failure

Heart failure is described as the heart's inability to pump enough blood for all of the body's needs (see the page on Heart Failure). In coronary heart disease, accumulation of atherosclerotic plaque in the coronary arteries may prevent heart regions from getting adequate circulation, ultimately resulting in cardiac damage and impaired pumping ability. Myocardial infarction may also damage the heart muscle, which could potentially lead to heart failure. Further, the diminished heart's capacity to pump blood in cases of dilated cardiomyopathy may lead to heart failure. Because physical exercise increases the demand on the weakened heart, measures of exercise tolerance are frequently used to monitor the severity of heart failure. Echocardiography is also used to determine the left ventricular ejection fraction (LVEF), an objective measure of the heart's pumping ability. An LVEF of less than 40% is indicative of systolic heart failure (52).

An abnormal acylcarnitine profile and a high acylcarnitine to free carnitine ratio in the blood of patients with heart failure have been linked to disease severity and poor prognosis (53-55). Addition of L-carnitine to standard medical therapy for heart failure has been evaluated in several clinical trials. A 2013 meta-analysis of 17 randomized, placebo-controlled studies in a total of 1,625 participants with heart failure found that oral L-carnitine (1.5-6 g/day for seven days to three years) significantly improved several measures of cardiac functional capacity (including exercise tolerance and markers of the left ventricle function), yet had no impact on all-cause mortality (56).

Angina pectoris

Angina pectoris is chest pain that occurs when the coronary blood supply is insufficient to meet the metabolic needs of the heart muscle (as with ischemic heart disease; see the page on Angina Pectoris) (57). In a prospective cohort study in over 4,000 participants with suspected angina pectoris, elevated concentrations of certain acylcarnitine intermediates in blood were associated with fatal and non-fatal acute myocardial infarction (58). In early studies, the addition of oral L-carnitine or propionyl-L-carnitine to pharmacologic therapy for chronic stable angina modestly improved exercise tolerance and decreased electrocardiographic signs of ischemia during exercise testing in some angina patients (59-61). Another early study examined hemodynamic and angiographic variables before, during, and after administering intravenous propionyl-L-carnitine (15 mg/kg body weight) in men with myocardial dysfunction and angina pectoris (62). In this study, propionyl-L-carnitine decreased myocardial ischemia, evidenced by significant reductions in ST-segment depression and left ventricular end-diastolic pressure (62). No recent and/or large-scale studies have been conducted to further examine the potential benefit of L-carnitine or propionyl-L-carnitine in the management of angina pectoris.

Intermittent claudication in peripheral arterial disease

In peripheral arterial disease, atherosclerosis of the arteries that supply the lower extremities may diminish blood flow to the point that the metabolic needs of exercising muscles are not sufficiently met, thereby leading to ischemic leg or hip pain known as claudication (see the page on Intermittent Claudication in Peripheral Arterial Disease) (63). Several clinical trials have found that treatment with propionyl-L-carnitine improves exercise tolerance in some patients with intermittent claudication. In a double-blind, placebo-controlled, dose-titration study, 1 to 3 g/day of oral propionyl-L-carnitine for 24 weeks was well tolerated and improved maximal walking distance in patients with intermittent claudication (64). In a randomized, placebo-controlled study of 495 patients with intermittent claudication, 2 g/day of propionyl-L-carnitine for 12 months significantly increased maximal walking distance and the distance walked prior to the onset of claudication in patients whose initial maximal walking distance was less than 250 meters (m), but no effect was seen in patients who had an initial maximal walking distance greater than 250 m (65). More recent trials have associated oral propionyl-L-carnitine supplementation (2 g/day for several months) with improved walking distance and claudication onset time (66, 67), as well as with higher pain-free walking distance and higher ankle-brachial index (a diagnostic measure of peripheral arterial disease) (68). Two 2013 systematic reviews of interventions concluded that the modest benefit of propionyl-L-carnitine on walking performance was equivalent or superior to that obtained with drugs approved for claudication in the US (e.g., pentoxyphylline, cilostazol) yet inferior to improvements seen with supervised exercise interventions (69, 70).

End-stage renal disease

L-Carnitine and short/medium-chain acylcarnitine molecules are removed from the circulation during hemodialysis. Both L-carnitine loss into the dialysate and impaired synthesis by the kidneys contribute to a progressive carnitine deficiency in patients with end-stage renal disease (ESRD) undergoing hemodialysis (71). The low clearance of long-chain acylcarnitine molecules leads to a high acylcarnitine-to-L-carnitine ratio that has been associated with a higher risk of cardiovascular mortality (72). Carnitine depletion in patients undergoing hemodialysis may lead to various conditions, such as muscle weakness and fatigue, plasma lipid abnormalities, and refractory anemia. A 2014 systematic review and meta-analysis of 31 randomized controlled trials in a total of 1,734 patients with ESRD found that L-carnitine treatment — administered either orally or intravenously — resulted in reductions of serum C-reactive protein (a marker of inflammation and predictor of mortality in patients undergoing hemodialysis) and LDL-cholesterol, although the latter was not deemed to be clinically relevant (73). There was no effect of L-carnitine on other serum lipids (i.e., total and HDL-cholesterol, triglycerides) and anemia-related indicators (i.e., hemoglobin concentration, hematocrit, albumin, and required dose of recombinant erythropoietin) (73).

The US National Kidney Foundation did not recommend routine administration of L-carnitine to subjects undergoing dialysis yet encouraged the development of trials in patients with select symptoms that do not respond to standard therapy, i.e., persistent muscle cramps or hypotension during dialysis, severe fatigue, skeletal muscle weakness or myopathy, cardiomyopathy, and anemia requiring large doses of erythropoietin (74, 75).

Finally, the use of L-carnitine (10-20 mg/kg body weight given as a slow bolus injection) is approved by the US FDA to treat L-carnitine deficiency in subjects with ESRD undergoing hemodialysis (76).

Peripheral neuropathy

Antiretroviral-related peripheral neuropathy

The use of certain antiretroviral agents (nucleoside analogs) has been associated with an increased risk of developing peripheral neuropathy in HIV-positive individuals (77, 78). Small, uncontrolled, open-label intervention studies have suggested a beneficial effect of acetyl-L-carnitine (ALCAR) in patients with painful neuropathies. An early uncontrolled study found that 10 out of 16 HIV-positive subjects with painful neuropathy reported improvement after three weeks of intravenous or intramuscular ALCAR treatment (79). Results from another uncontrolled intervention in 21 HIV-positive patients suggested that long-term (two to four years) oral ALCAR supplementation (1.5 g/day) may be a beneficial adjunct to antiretroviral therapy to improve neuropathic symptoms in some HIV-infected individuals (80, 81). Additionally, two small studies in participants presenting with antiretroviral-induced neuropathy found significant reduction in subjects' mean pain intensity with oral ALCAR (1-3 g/day) for 4 to 24 weeks, but no effect on objective neurophysiological parameters was found (82, 83).

A double-blind, placebo-controlled trial in 90 HIV-positive patients with symptomatic distal symmetrical polyneuropathy found no benefit of intramuscular injection with 1 g/day of ALCAR for two weeks in the intention-to-treat analysis, but there was some pain relief in the group of 66 patients who completed the trial (84). Large-scale, controlled studies are needed before any conclusions can be drawn.

Diabetic peripheral neuropathy

Peripheral nerve dysfunction occurs in about 50% of people with diabetes mellitus, and chronic neuropathic pain is present in about one-third of people with diabetic peripheral neuropathy (85). Advanced stages of diabetic peripheral neuropathy can lead to recurrent foot ulcers and infections, and eventually amputations (86). A 2019 systematic review (87) identified three placebo-controlled interventions that examined the effect of oral supplementation with acetyl-L-carnitine (ALCAR; 1.5-3.0 g/day for one year) in individuals with diabetic peripheral neuropathy (3, 88). Low-quality evidence suggested a lower level of pain with ALCAR, as measured with a visual scale analog. Low-quality evidence from another trial that compared the effect of ALCAR (1.5 g/day) with that of methylcobalamin (1.5 mg/day) for 24 weeks suggested no difference between treatments regarding the extent of functional disability (using the Neuropathy Disability Scale) or measures of symptom quality and severity (using the Neuropathy Symptom Scale) (89).

Chemotherapy-induced peripheral neuropathy

A few randomized, double-blind, placebo-controlled trials have examined whether ALCAR might help prevent or treat chemotherapy-induced peripheral neuropathy. A trial in 150 participants with either ovarian cancer or castration-resistant prostate cancer found no evidence that ALCAR (1g every 3 days) given with the anticancer drug sagopilone (for up to six cycles of treatment) reduced the overall risk of peripheral neuropathy compared to a placebo (90). However, ALCAR reduced the risk of high-grade sagopilone-induced neuropathy (90). In contrast, another trial in 409 women with breast cancer found that ALCAR (3 g/day for 24 weeks) increased anticancer drug (taxanes)-induced peripheral neuropathy and decreased measures of functional status compared to placebo (91). A follow-up study reported that the negative impact of 24-week treatment with ALCAR was still observed at week 52; however, no differences between ALCAR and placebo were apparent at week 104 (92). Finally, one trial in 239 participants already suffering from chemotherapy-induced peripheral neuropathy reported a reduction in the severity of neuropathic symptoms with ALCAR (3 g/day for eight weeks) compared to placebo (93). Improvements in electrophysiological parameters were also observed with ALCAR treatment (93).

The results from these trials are conflicting and thus difficult to interpret. The efficacy of ALCAR in the prevention and treatment of chemotherapy-induced peripheral neuropathy remains to be established (94).

Depression

A 2018 meta-analysis identified 12 randomized controlled trials, including 791 participants, that examined the effect of ALCAR on symptoms of depression (95). Evidence from nine trials suggested a reduction in depressive symptoms with ALCAR (3 g/day for a median 8 weeks) compared to a placebo. Three trials that compared ALCAR treatment (1-3 g/day for 7-12 weeks) and antidepressant medications found ALCAR was as effective as antidepressants in treating depressive symptoms (95). Another meta-analysis of trials that compared the safety profile of antidepressants found evidence of fewer adverse effects, and consequently, better adherence to treatment with ALCAR compared to placebo and in contrast to classical pharmaceutical agents (96).

Alzheimer's disease

The metabolomic profiling of acylcarnitine molecules showed variations in serum concentrations of subjects along the continuum from cognitively healthy to affected by Alzheimer's disease (97). Changes in the blood concentrations of specific acylcarnitines in subjects with either subjective memory complaints, mild cognitive impairment, or Alzheimer's disease, compared to cognitively healthy peers may reflect changes in the transport of fatty acids into the mitochondria and/or impairments in energy production. Several clinical trials conducted in the 1990s examined the effect of acetyl-L-carnitine (ALCAR) treatment on the cognitive performance of patients clinically diagnosed with Alzheimer's disease. Early, small trials suggested a beneficial effect of ALCAR with respect to cognitive decline (98-100), whereas later, larger trials found little-to-no effect compared to placebo (101-103). However, a 2003 systematic review highlighted differences in methodologies between early and later studies that make it difficult to compare results (104). Nevertheless, the pooled analysis of 16 trials suggested improvements in the summary measure of patients' global functioning (assessed with the Clinical Global Impressions [CGI-I] scale) after 12 and 24 weeks of (but not after 52 weeks) of ALCAR treatment (1-3 g/day) and in cognitive performance (assessed with the Mini-Mental State Examination [MMSE] scale) after 24 weeks (but not at 12 or 52 weeks) (104). A 2003 meta-analysis of 21 trials found that ALCAR was superior to placebo in several psychometric tests assessing global patient functioning, attention, memory, and some intellectual functions (105).

Hepatic encephalopathy

Hepatic encephalopathy refers to the occurrence of a spectrum of neuropsychiatric signs or symptoms in individuals with acute or chronic liver disease (106). Subclinical hepatic encephalopathy may not feature any symptoms beyond abnormal behavior on psychometric tests or symptoms that are nonspecific in nature. In contract, overt hepatic encephalopathy can present with disorientation, obvious personality change, inappropriate behavior, somnolence, stupor, confusion, and coma (106). Changes in mental status are thought to be caused by the liver failing to detoxify neurotoxic compounds like ammonia. A 2019 systematic review of five placebo-controlled trials conducted by one group of investigators examined the effect of acetyl-L-carnitine (ALCAR) in 398 participants with cirrhosis and portal hypertension (high blood pressure in the portal vein) and presenting with either subclinical or overt hepatic encephalopathy. ALCAR was either administered orally (4 g/day for 90 days) in four trials or intravenously (4 g/day for three days) in one trial. ALCAR was found to significantly reduce blood ammonium concentration compared to placebo. However, none of the trials reported on serious adverse outcomes, including mortality. Additionally, the evidence was too limited to assess the impact on quality of life or mental and physical fatigue.

Cancer-related fatigue

Fatigue is not uncommon in people who have undergone chemotherapy and survived cancer, with fatigue symptoms depending on the specific type of cancer and treatment. Cancer-related fatigue can persist well beyond the end of chemotherapy and be associated with cognitive and functional decline, insomnia, depression, and a reduction in the quality of life (107). A 2017 systematic review and meta-analysis identified 12 intervention studies that assessed the effect of L-carnitine or ALCAR on cancer-related fatigue (reported as a primary or secondary outcome) in cancer survivors (108). Three studies had no control arm, eight studies were open-label, and eight studies included fewer than 100 participants. Overall, only three studies were deemed of good quality. The meta-analysis of these three randomized, double-blind, placebo-controlled trials found no effect of L-carnitine (0.25-4 g/day for 1 week to 3 months) or ALCAR (3 g/day for 6 months) on the level of cancer-related fatigue (108).

Infertility

L-Carnitine is concentrated in the epididymis, where sperm mature and acquire their motility (109). An early cross-sectional study of 101 fertile and infertile men found that L-carnitine concentrations in semen were positively correlated with the number of sperm, the percentage of motile sperm, and the percentage of normal appearing sperm in the sample (110), suggesting that L-carnitine may play an important role in male fertility. One placebo-controlled, double-blind, cross-over trial in 86 subjects with fertility issues found that supplementation with L-carnitine (2 g/day) for two months improved sperm quality, as evidenced by increases in sperm concentration and motility (111). In another placebo-controlled trial conducted by the same group, similar improvements in sperm motility were observed in participants supplemented with 2g/day of L-carnitine and 1 g/day of acetyl-L-carnitine (ALCAR) for six months (112). In both trials, the effect of carnitine was greater in the most severe cases of asthenozoospermia (reduced sperm motility) at baseline (111, 112). Another placebo-controlled, double-blind, randomized study in 44 men with idiopathic asthenozoospermia found an increase in sperm motility in those given ALCAR alone (3 g/day) or ALCAR (1 g/day) plus L-carnitine (2 g/day) compared to those given L-carnitine alone (2 g/day) or a placebo (113). However, a pooled analysis of the two trials that employed ALCAR found no significant effect of ALCAR and L-carnitine on sperm concentration, motility, and morphology (114). Evidence from larger scale clinical trials is still needed to determine whether L-carnitine and ALCAR could play a role in the treatment of male infertility.

Physical health

Frailty

Frailty is a syndrome prevalent among geriatric populations and characterized by a functional decline and a loss of independence to perform the activities of daily living. Frailty in individuals may include at least three of the following symptoms: unintentional weight loss, exhaustion (poor endurance), weakness (low grip strength), slowness, and physical inactivity (115). It is believed that early stages of frailty are amenable to interventions that could avert adverse outcomes, including the increased risk of hospitalization and premature death (116). The suggestion that carnitine deficiency may lead to frailty through mitochondrial dysfunction (117) has been examined in one trial. This randomized, double-blind, placebo-controlled trial in 58 older adults identified as "pre-frail" found an decrease in a Frailty Index score and an improvement in the hand grip test in individuals supplemented with L-carnitine (1.5 g/day) over 10 weeks but not in those given a placebo (118). However, there was no difference in Frailty Index and hand grip test scores between supplemental L-carnitine and placebo groups.

Skeletal muscle wasting

Loss of skeletal muscle mass is associated with a decrease in muscle strength and occurs with aging (119), as well as in several pathological conditions (120-122). Based on preclinical studies, it has been suggested that L-carnitine supplementation could limit the imbalance between protein anabolism (synthesis) and catabolism (degradation) that leads to skeletal muscle wasting (42). A randomized, double-blind, placebo-controlled trial in 28 older women (ages, 65-70 years) found no effect of L-carnitine supplementation (1.5 g/day for 24 weeks) on serum pro-inflammatory cytokine concentrations, body mass and composition (lean [fat-free] mass and skeletal muscle mass), or measures of skeletal muscle strength (123). In contrast, a retrospective cohort study in patients with cirrhosis found a reduced rate of skeletal muscle loss over at least six months in those who were administered L-carnitine (N=35; mean dose, 1.02 g/day) compared to those who were not (124). Of note, supplementation with L-carnitine was given in patients with cirrhosis to control hyperammonemia (N=27), to reduce muscle cramps (N=6), or to prevent carnitine deficiency (N=2). One major limitation of this study beyond its retrospective design is that patients who received L-carnitine had a significantly different clinical presentation; in particular, liver dysfunction was significantly more severe in these patients than in those who were not supplemented (124).

Muscle cramps

Muscle cramps are involuntary and painful contractions of skeletal muscles. Two uncontrolled studies conducted in participants with cirrhosis found that L-carnitine supplementation was safe to use at doses of 0.9 to 1.2 g/day for eight weeks (125) and 1 g/day for 24 weeks (126) and might be considered to control the frequency of cramps. However, whether supplemental L-carnitine can be efficacious to limit the incidence of muscle cramps in patients with cirrhosis remains unknown. An open-label, non-randomized trial in 69 patients with either type 1 or type 2 diabetes mellitus found a reduction in the incidence of muscle cramps and an improvement in the quality of life of those prescribed 0.6 g/day of L-carnitine for four months compared to controls (127). In contrast, there is little evidence to date to suggest that supplemental L-carnitine could reduce muscle cramps in patients undergoing hemodialysis (128). Well-designed trials are necessary to examine whether L-carnitine could be helpful in the management of cramps.

Physical performance

Interest in the potential of L-carnitine supplementation to improve athletic performance is related to its important roles in energy metabolism. A number of small, poorly controlled studies have reported that either acute (dose given one hour before exercise bout) or short-term (two to three weeks) supplementation with L-carnitine (2 to 4 g/day) supported energy production, cardiorespiratory fitness, and endurance capacity during physical exercise (reviewed in 129). However, in a double-blind, placebo-controlled trial in 32 healthy adults, propionyl-L-carnitine (1 g/day or 3 g/day) for eight weeks did not improve aerobic or anaerobic exercise performance (130). An intervention study compared the effect of L-carnitine supplementation (2 g/day for 12 weeks) on plasma and skeletal muscle carnitine concentrations and physical performance between 16 vegetarian and 8 omnivorous male participants (131). At baseline, plasma carnitine concentration was about 10% lower in vegetarian compared to omnivorous participants. However, the content carnitine in skeletal muscle, phosphocreatine, ATP, glycogen, and lactate, as well as measures of physical performance during exercise were equivalent between vegetarians and omnivores. While L-carnitine supplementation normalized plasma carnitine concentration in vegetarians to that observed in omnivores, there was no effect on energy metabolism and physical performance compared to no supplementation and between vegetarians and omnivores (131).

Sources

Biosynthesis

The normal rate of L-carnitine biosynthesis in humans ranges from 0.16 to 0.48 mg/kg of body weight/day (4). Thus, a 70 kg (154 1b) person would synthesize between 11 and 34 mg of carnitine per day. This rate of synthesis, combined with efficient (95%) L-carnitine reabsorption by the kidneys, is sufficient to prevent deficiency in generally healthy people, including strict vegetarians (132).

Food sources

Meat, poultry, fish, and dairy products are the richest sources of L-carnitine, while fruit, vegetables, and grains contain relatively little L-carnitine. Omnivorous diets have been found to provide 23 to 135 mg/day of L-carnitine for an average 70 kg person, while strict vegetarian diets may provide as little as 1 mg/day for a 70 kg person (8). Between 54% and 86% of L-carnitine from food is absorbed, compared to 5%-25% from oral supplements (0.6-7 g/day) (13). Non-milk-based infant formulas (e.g., soy formulas) should be fortified so that they contain 11 mg/L of L-carnitine. Some carnitine-rich foods and their carnitine content in milligrams (mg) are listed in **Table 1**.

Table 1. L-Carnitine Content of Selected Foods

Food	Serving	L-Carnitine (mg)
Beef steak	3 ounces*	81
Ground beef	3 ounces	80
Pork	3 ounces	24
Canadian bacon	3 ounces	20
Milk (whole)	8 fluid ounces (1 cup)	8
Fish (cod)	3 ounces	5
Chicken breast	3 ounces	3
Ice cream	4 ounces (½ cup)	3
Avocado	1 medium	2
American cheese	1 ounce	1
Whole-wheat bread	2 slices	0.2
Asparagus	6 spears (½ cup)	0.2
*A three-ounce serving of meat is about the size of a deck of cards.		

Supplements

Intravenous L-carnitine

Intravenous L-carnitine is available by prescription only for the treatment of primary and secondary L-carnitine deficiencies (76).

Oral L-carnitine

Oral L-carnitine is available by prescription for the treatment of primary and secondary L-carnitine deficiencies (76). It is also available without a prescription as a nutritional supplement; supplemental doses usually range from 0.5 to 2 g/day.

Acetyl-L-carnitine

Acetyl-L-carnitine (ALCAR) is available without a prescription as a nutritional supplement. In addition to providing L-carnitine, it provides acetyl groups that may be used in the formation of the neurotransmitter, acetylcholine. Supplemental doses usually range from 0.5 to 2 g/day (133).

Propionyl-L-carnitine

Propionyl-L-carnitine is not approved by the US FDA for use as a drug to prevent or treat any condition. It is, however, available without prescription as a nutritional supplement.

See Figure 1 for the chemical structures of L-carnitine, acetyl-L-carnitine, and propionyl-L-carnitine.

Safety

Adverse effects

In general, L-carnitine appears to be well tolerated; no toxic effects have been reported in relation to intakes of high doses of L-carnitine. L-Carnitine supplementation may cause mild gastrointestinal symptoms, including nausea, vomiting, abdominal cramps, and diarrhea. Supplements providing more than 3 g/day may cause a "fishy" body odor. Acetyl-L-carnitine (ALCAR) has been reported to increase agitation in some Alzheimer's disease patients (133). Despite claims that L-carnitine or ALCAR might increase seizures in some individuals with seizure disorders (133), these are not supported by any scientific evidence (134). Only the L-isomer of carnitine is biologically active; the D-isomer may actually compete with L-carnitine for absorption and transport, thereby increasing the risk of L-carnitine deficiency (4). Supplements containing a mixture of the D- and L-isomers (D,L-carnitine) have been associated with muscle weakness in patients with kidney disease. Long-term studies examining the safety of ALCAR supplementation in pregnant and breast-feeding women are lacking (133).

Drug interactions

Pivalic acid combines with L-carnitine and is excreted in the urine as pivaloylcarnitine, thereby increasing L-carnitine losses (see also Secondary carnitine deficiency). Consequently, prolonged use of pivalic acid-containing antibiotics, including pivampicillin, pivmecillinam, pivcephalexin, and cefditoren pivoxil (Spectracef), can lead to secondary L-carnitine deficiency (135). The anticonvulsant valproic acid (Depakene) interferes with L-carnitine biosynthesis in the liver and forms with L-carnitine a valproylcarnitine ester that is excreted in the urine. However, L-carnitine supplements are necessary only in a subset of patients taking valproic acid. Risk factors for L-carnitine deficiency with valproic acid include young age (<2 years), severe neurological problems, use of multiple antiepileptic drugs, poor nutrition, and consumption of a ketogenic diet (135). There is insufficient evidence to suggest that nucleoside analogs used in the treatment of HIV infection (i.e., zidovudine [AZT], didanosine [ddI], zalcitabine [ddC], and stavudine [d4T] or certain cancer chemotherapy agents (i.e., ifosfamide, cisplatin) increase the risk of secondary L-carnitine deficiency (135).

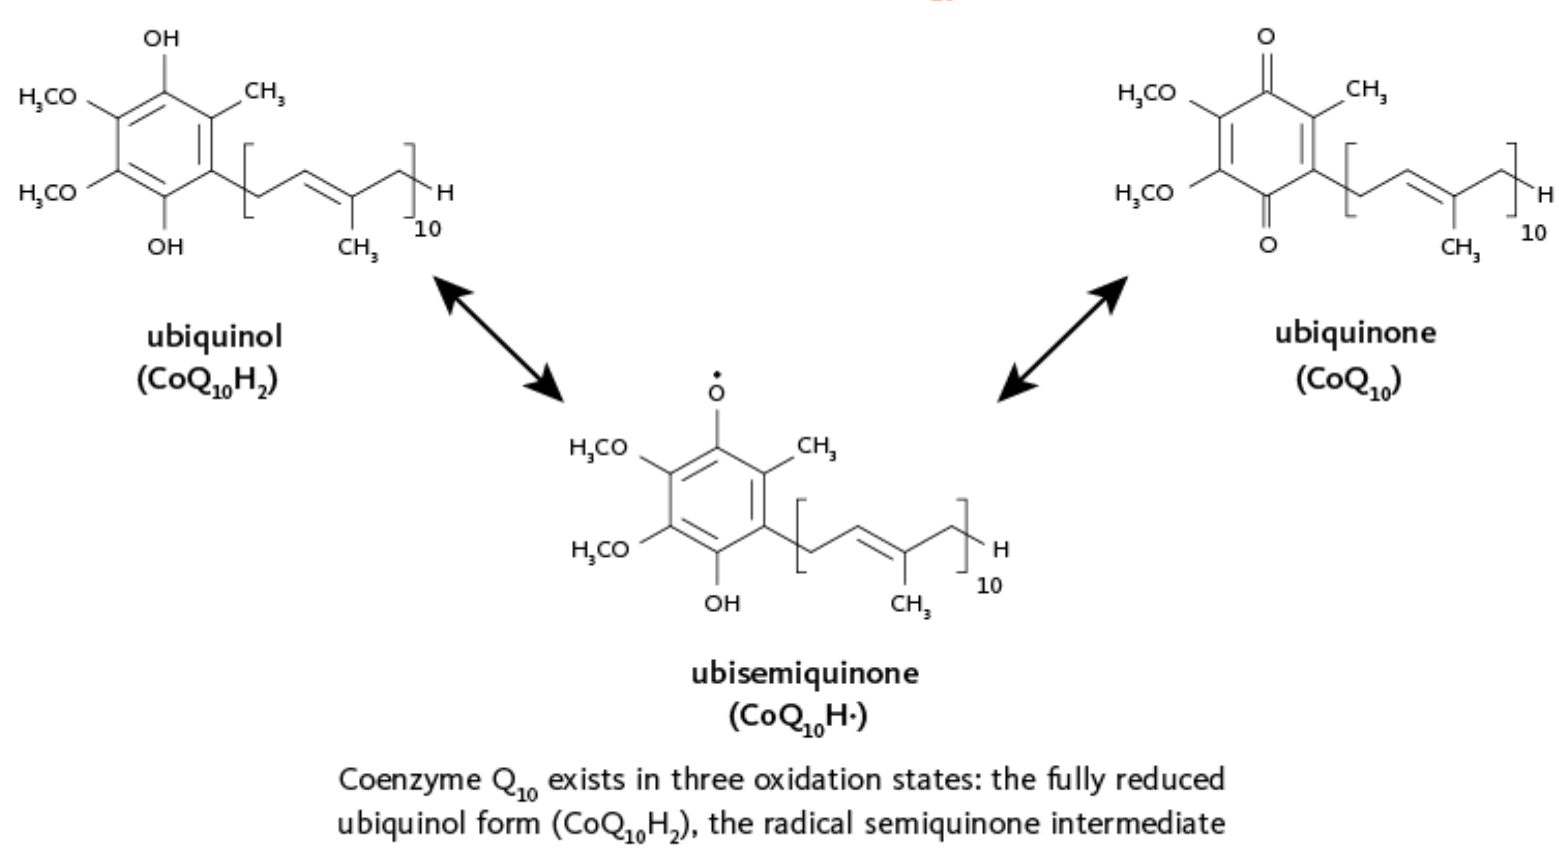
Summary

- Coenzyme Q$_{10}$ is a fat-soluble compound that is synthesized by the body and can be obtained from the diet. *(More information)*
- Coenzyme Q$_{10}$ plays a central role in mitochondrial oxidative phosphorylation and the production of adenosine triphosphate (ATP). It also functions as an antioxidant in cell membranes and lipoproteins. *(More information)*
- Endogenous synthesis and dietary intake provide sufficient coenzyme Q$_{10}$ to prevent deficiency in healthy people, although coenzyme Q$_{10}$ concentrations in tissues decline with age. *(More information)*
- Oral supplementation of coenzyme Q$_{10}$ increases coenzyme Q$_{10}$ concentrations in plasma and lipoproteins, but it is unclear whether concentrations in peripheral tissues are increased, especially in healthy individuals. *(More information)*
- Oral high-dose coenzyme Q$_{10}$ is usually effective to treat mitochondrial disorders that are caused by mutations in coenzyme Q$_{10}$ biosynthetic genes. *(More information)*
- There is some evidence to suggest that coenzyme Q$_{10}$ supplementation may be a useful adjunct to conventional medical therapy for congestive heart failure and in patients undergoing coronary artery bypass graft surgery. *(More information)*
- There are currently no proven therapeutic benefits of coenzyme Q$_{10}$ supplementation in diabetes mellitus, neurodegenerative diseases, inherited ataxias, or breast cancer. *(More information)*
- Coenzyme Q$_{10}$ supplementation does not appear to improve athletic performance. *(More information)*
- Although coenzyme Q$_{10}$ supplements are relatively safe, they may decrease the anticoagulant efficacy of warfarin. *(More information)*
- The use of cholesterol-lowering medications called statins can decrease circulating coenzyme Q$_{10}$ concentrations. However, there is no evidence that this causes any adverse side effects in statin-treated patients. *(More information)*

Introduction

Coenzyme Q$_{10}$ is a member of the ubiquinone family of compounds. All animals, including humans, can synthesize ubiquinones, hence, coenzyme Q$_{10}$ is not considered a vitamin (1). The name ubiquinone refers to the ubiquitous presence of these compounds in living organisms and their chemical structure, which contains a functional group known as a benzoquinone. Ubiquinones are fat-soluble molecules with anywhere from 1 to 12 isoprene (5-carbon) units. The ubiquinone found in humans, ubidecaquinone or coenzyme Q$_{10}$, has a "tail" of 10 isoprene units (a total of 50 carbon atoms) attached to its benzoquinone "head" (**Figure 1**) (1).

Figure 1. The Different Redox Forms of Coenzyme Q$_{10}$



Coenzyme Q$_{10}$ exists in three oxidation states: the fully reduced ubiquinol form (CoQ$_{10}$H$_2$), the radical semiquinone intermediate (CoQ$_{10}$H·), and the fully oxidized ubiquinone form (CoQ$_{10}$).

[Figure 1 - Click to Enlarge]

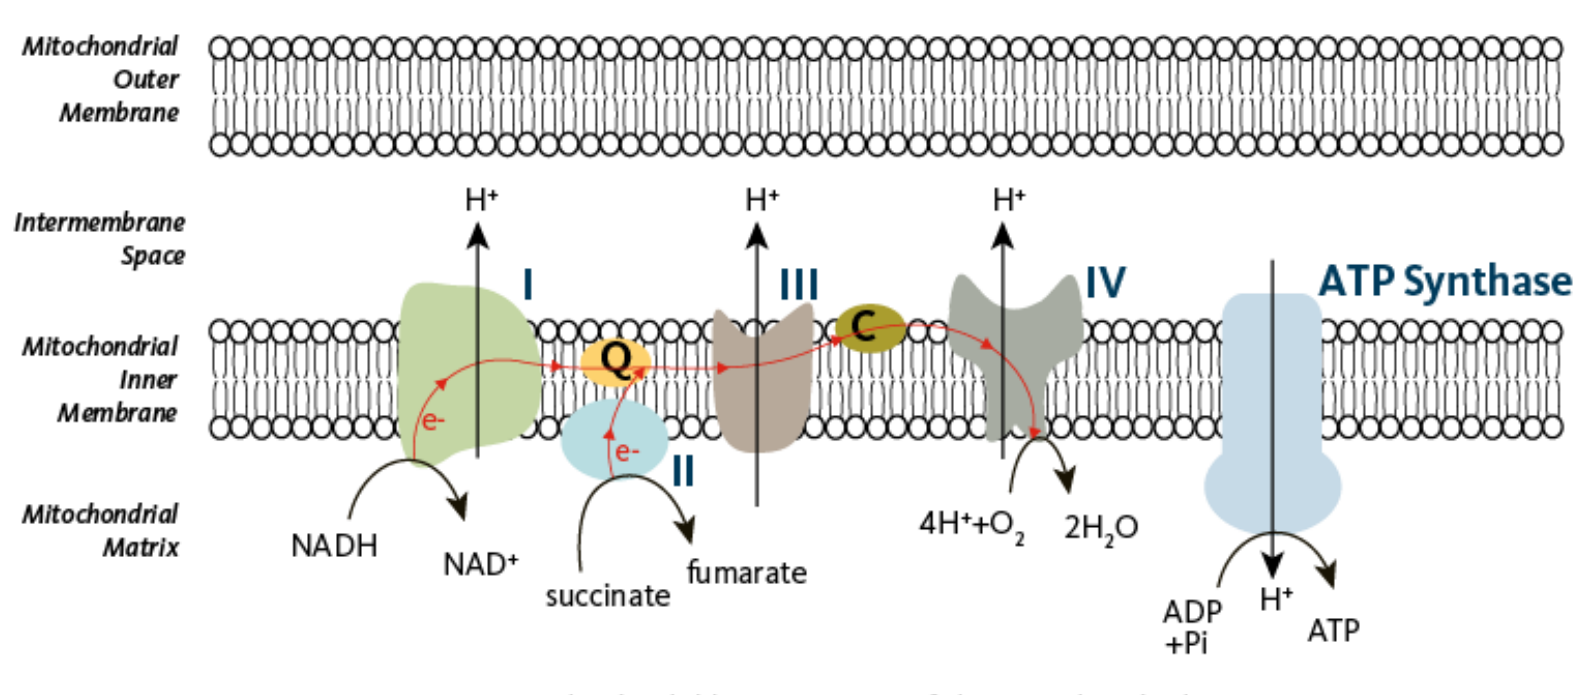
Biological Activities

Coenzyme Q$_{10}$ is soluble in lipids (fats) and is found in virtually all cell membranes, including mitochondrial membranes. The ability of the benzoquinone head group of coenzyme Q$_{10}$ to accept and donate electrons is a critical feature to its function. Coenzyme Q$_{10}$ can exist in three oxidation states (**Figure 1**): (i) the fully reduced ubiquinol form, CoQ$_{10}$H$_2$; (ii) the radical semiquinone intermediate, CoQ$_{10}$H·; and (iii) the fully oxidized ubiquinone form, CoQ$_{10}$.

Mitochondrial ATP synthesis

The conversion of energy from carbohydrates and fats to ATP, the form of energy used by cells, requires the presence of coenzyme Q$_{10}$ in the inner mitochondrial membrane. As part of the mitochondrial electron transport chain, coenzyme Q$_{10}$ accepts electrons from reducing equivalents generated during fatty acid and glucose metabolism and then transfers them to electron acceptors. At the same time, coenzyme Q$_{10}$ contributes to transfer protons (H$^+$) from the mitochondrial matrix to the intermembrane space, creating a proton gradient across the inner mitochondrial membrane. The energy released when the protons flow back into the mitochondrial interior is used to form ATP (**Figure 2**) (1). In addition to its role in ATP synthesis, mitochondrial coenzyme Q$_{10}$ mediates the oxidation of dihydroorotate to orotate in the *de novo* pyrimidine synthesis.

Figure 2. Mitochondrial Electron Transport Chain



Coenzyme Q$_{10}$ is a lipid-soluble component of the mitochondrial inner membrane that is critical to electron transport (in red) in the mitochondrial respiratory chain. Coenzyme Q$_{10}$ carries electrons from complexes I and II to complex III, thus participating in ATP production. *C, cytochrome C; e-, electron; H$^+$, proton; Q, coenzyme Q$_{10}$.*

[Figure 2 - Click to Enlarge]

Lysosomal function

Lysosomes are organelles within cells that are specialized for the digestion of cellular debris. The digestive enzymes within lysosomes function optimally at an acidic pH, meaning they require a permanent supply of protons. The lysosomal membranes that separate those digestive enzymes from the rest of the cell contain relatively high concentrations of coenzyme Q$_{10}$. Research suggests that coenzyme Q$_{10}$ plays an important role in the transport of protons across lysosomal membranes to maintain the optimal pH (2, 3).

Antioxidant functions

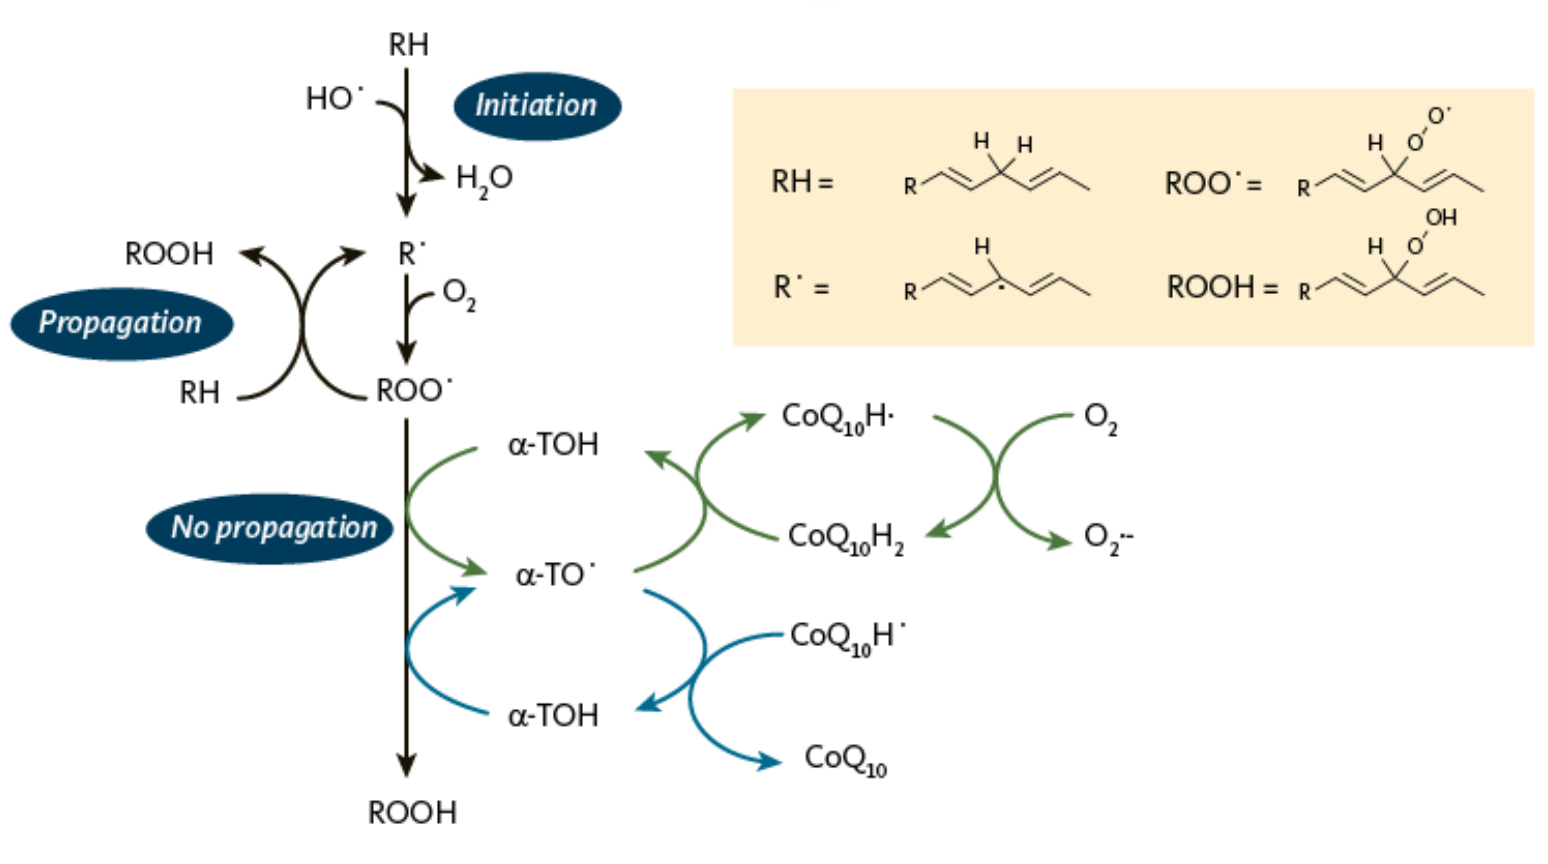
In its reduced form (CoQ$_{10}$H$_2$), coenzyme Q$_{10}$ is an effective fat-soluble antioxidant that protects cell membranes and lipoproteins from oxidation. The presence of a significant amount of CoQ$_{10}$H$_2$ in cell membranes, along with enzymes capable of reducing oxidized CoQ$_{10}$ back to CoQ$_{10}$H$_2$ (i.e., NAD(P)H oxidoreductases), supports the idea that CoQ$_{10}$H$_2$ is an important cellular antioxidant (4). CoQ$_{10}$H$_2$ has been found to inhibit lipid peroxidation when cell membranes and low-density lipoproteins (LDL) are exposed to oxidizing conditions. When LDL is oxidized, CoQ$_{10}$H$_2$ is the first antioxidant consumed. In isolated mitochondria, coenzyme Q$_{10}$ can protect membrane proteins and mitochondrial DNA from the oxidative damage that accompanies lipid peroxidation (5). Moreover, when present, CoQ$_{10}$H$_2$ was found to limit the formation of oxidized lipids and the consumption of α-tocopherol (a form of vitamin E with antioxidant properties) (6). Indeed, in addition to neutralizing free radicals directly, CoQ$_{10}$H$_2$ is capable of regenerating antioxidants like α-tocopherol and ascorbate (vitamin C) (4). Finally, the role of coenzyme Q$_{10}$ as an antioxidant is also exemplified by recent evidence showing that mitochondrial coenzyme Q$_{10}$ deficiency causes an increased production of mitochondrial superoxide radical anion ($O_2^{\bullet-}$) which might be driving insulin resistance in adipose and muscle tissues (7).

Nutrient interactions

Vitamin E

α-Tocopherol (vitamin E) and coenzyme Q$_{10}$ are the principal fat-soluble antioxidants in membranes and lipoproteins. When α-tocopherol (α-TOH) neutralizes a free radical, such as a lipid peroxyl radical (LOO·), it becomes oxidized itself, forming α-TO·, which can in turn promote the oxidation of lipoproteins under certain conditions in the test tube, thus propagating a chain reaction. However, when the reduced form of coenzyme Q$_{10}$ (CoQ$_{10}$H$_2$) reacts with α-TO·, α-TOH is regenerated and the semiquinone radical (CoQ$_{10}$H·) is formed. It is possible for CoQ$_{10}$H· to react with oxygen (O$_2$) to produce superoxide anion radical ($O_2^{\cdot -}$), which is a less reactive pro-oxidant than LOO·. However, CoQ$_{10}$H· can also reduce α-TO· back to α-TOH, resulting in the formation of fully oxidized coenzyme Q$_{10}$ (CoQ$_{10}$), which does not react with O$_2$ to form $O_2^{\cdot -}$ (**Figure 3**) (6, 8).

Figure 3. Antioxidant Activity of Coenzyme Q$_{10}$



The peroxidation of unsaturated lipids leads to the formation of lipid peroxyl radicals (ROO˙) that easily diffuse in biological systems. Peroxyl radicals react 1,000 times faster with α-tocopherol than with unsaturated lipids (RH). The hydroxyl group in the chromanol head of α-tocopherol (reduced form, α-TOH) can donate hydrogen to scavenge lipid peroxyl radicals, which halts their propagation in membranes and circulating lipoproteins. The presence of other antioxidants, such as coenzyme Q$_{10}$ (ubiquinol), is required to regenerate the antioxidant capacity of α-tocopherol.

In green: when the reduced form of coenzyme Q$_{10}$ (CoQ$_{10}$H$_2$) reacts with α-TO (oxidized α-tocopherol), α-TOH is regenerated and the semiquinone radical (ubisemiquinone, CoQ$_{10}$H˙) is formed. CoQ$_{10}$H˙ can react with oxygen (O$_2$) and produce superoxide ($O_2^{\cdot -}$), which is a much less oxidizing radical than ROO˙.

In blue: alternatively, CoQH˙ can also reduce α-TO˙ back to α-TOH, resulting in the formation of CoQ$_{10}$ (fully oxidized coenzyme Q$_{10}$ form), which does not react with O$_2$ to form superoxide.

[Figure 3 - Click to Enlarge]

Deficiency

Coenzyme Q$_{10}$ deficiency has not been described in the general population, so it is generally assumed that normal biosynthesis, with or without a varied diet, provides sufficient coenzyme Q$_{10}$ to sustain energy production in healthy individuals (9).

Primary coenzyme Q$_{10}$ deficiency is a rare genetic disorder caused by mutations in genes involved in coenzyme Q$_{10}$ biosynthetic pathway. To date, mutations in at least nine of these genes have been identified (1). As a result, primary coenzyme Q$_{10}$ deficiency is a clinically heterogeneous disorder that includes five major phenotypes: (i) severe infantile multi-systemic disease, (ii) encephalomyopathy, (iii) cerebellar ataxia, (iv) isolated myopathy, and (v) nephrotic syndrome. Whereas most mitochondrial respiratory chain disorders are hardly amenable to treatments, oral coenzyme Q$_{10}$ supplementation has been shown to improve muscular symptoms in some (yet not all) patients with primary coenzyme Q$_{10}$ deficiency (10). Neurological symptoms in patients with cerebellar ataxia are only partially relieved by coenzyme Q$_{10}$ (CoQ$_{10}$H$_2$) supplementation (10).

Secondary coenzyme Q$_{10}$ deficiency results from mutations or deletions in genes that are not directly related to coenzyme Q$_{10}$ biosynthetic pathway. Evidence of secondary coenzyme Q$_{10}$ deficiency has been reported in several mitochondrial disorders, such as mitochondrial DNA depletion syndrome, Kearns-Sayre syndrome, or multiple acyl-CoA dehydrogenase deficiency (MADD) (10). Secondary coenzyme Q$_{10}$ deficiency has also been identified in non-mitochondrial disorders, such as cardiofaciocutaneous syndrome and Niemann-Pick-type C disease (11). Because the therapeutic potential of supplemental coenzyme Q$_{10}$ is limited to its capacity to restore electron transfer in a defective mitochondrial respiratory chain and/or to increase antioxidant defense, patients with secondary coenzyme Q$_{10}$ deficiency may fail to respond to supplementation (see Disease Treatment).

Coenzyme Q$_{10}$ concentrations have been found to decline gradually with age in a number of different tissues (5, 12), but it is unclear whether this age-associated decline constitutes a deficiency (see Disease Prevention) (13). Decreased plasma concentrations of coenzyme Q$_{10}$ have been observed in individuals with diabetes mellitus, cancer, and congestive heart failure (see Disease Treatment). Lipid-lowering medications that inhibit the activity of 3-hydroxy-3-methylglutaryl (HMG)-coenzyme A (CoA) reductase (statins), a critical enzyme in both cholesterol and coenzyme Q$_{10}$ biosynthesis, decrease plasma coenzyme Q$_{10}$ concentrations (see HMG-CoA reductase inhibitors [statins]), although it remains unproven that this has any clinical implications.

Disease Prevention

Aging

According to the free radical and mitochondrial theories of aging, oxidative damage of cell structures by reactive oxygen species (ROS) plays an important role in the functional declines that accompany aging (14). ROS are generated by mitochondria as a byproduct of ATP production. If not neutralized by antioxidants, ROS may damage mitochondria over time, causing them to function less efficiently and to generate more damaging ROS in a self-perpetuating cycle. Coenzyme Q$_{10}$ plays an important role in mitochondrial ATP synthesis and functions as an antioxidant in mitochondrial membranes (see Biological Activities). One of the hallmarks of aging is a decline in energy metabolism in many tissues, especially liver, heart, and skeletal muscle. Tissue concentrations of coenzyme Q$_{10}$ have been found to decline with age, thereby accompanying age-related declines in energy metabolism (12). Early animal studies have not been able to demonstrate an effect of lifelong dietary supplementation with coenzyme Q$_{10}$ on the lifespan of rats or mice (15-17). Nonetheless, more recent studies have suggested that supplemental coenzyme Q$_{10}$ could promote mitochondrial biogenesis and respiration (18, 19) and delay senescence in transgenic mice (19). Presently, there is limited scientific evidence to suggest that coenzyme Q$_{10}$ supplementation prolongs life or prevents age-related functional declines in humans. In a small randomized controlled trial, elderly individuals (>70 years) who received a combination of selenium (100 μg/day) and coenzyme Q$_{10}$ (200 mg/day) for four years reported an improvement in vitality, physical performance, and quality of life (20). Further, a 12-year follow-up of these participants showed a reduction in cardiovascular mortality with supplemental selenium and coenzyme Q$_{10}$ compared to placebo (21).

Atherosclerosis

Oxidative modification of low-density lipoproteins (LDL) in arterial walls is thought to represent an early event leading to the development of atherosclerosis. Reduced coenzyme Q$_{10}$ (CoQ$_{10}$H$_2$) inhibits the oxidation of LDL in the test tube (*in vitro*) and works together with α-tocopherol (α-TOH) to inhibit LDL oxidation by regenerating α-TO· back to α-TOH. In the absence of a co-antioxidant, such as CoQ$_{10}$H$_2$ or vitamin C, α-TO· can, under certain conditions, promote the oxidation of LDL *in vitro* (6). Supplementation with coenzyme Q$_{10}$ increases the concentration of CoQ$_{10}$H$_2$ in human LDL (22). Studies in apolipoprotein E-deficient mice, an animal model of atherosclerosis, found that coenzyme Q$_{10}$ supplementation with supra-pharmacological amounts of coenzyme Q$_{10}$ inhibited lipoprotein oxidation in the blood vessel wall and the formation of atherosclerotic lesions (23). Interestingly, co-supplementation of these mice with α-TOH and coenzyme Q$_{10}$ was more effective in inhibiting atherosclerosis than supplementation with either α-TOH or coenzyme Q$_{10}$ alone (24).

Another important step in the development of atherosclerosis is the recruitment of immune cells known as monocytes into the blood vessel walls. This recruitment is dependent in part on monocyte expression of cell adhesion molecules (integrins). Supplementation of 10 healthy men and women with 200 mg/day of coenzyme Q$_{10}$ for 10 weeks resulted in significant decreases in monocyte expression of integrins, suggesting another potential mechanism for the inhibition of atherosclerosis by coenzyme Q$_{10}$ (25). Although coenzyme Q$_{10}$ supplementation shows promise as an inhibitor of LDL oxidation and atherosclerosis, more research is needed to determine whether coenzyme Q$_{10}$ supplementation can inhibit the development or progression of atherosclerosis in humans.

Disease Treatment

Primary and secondary coenzyme Q$_{10}$ deficiencies

Inherited coenzyme Q$_{10}$ deficiencies are rare diseases that are clinically and genetically heterogeneous (see Deficiency). In individuals with primary coenzyme Q$_{10}$ deficiency, early treatment with high-dose coenzyme Q$_{10}$ supplementation (10–30 mg/kg/day in children and 1.2–3.0 g/day in adults) may improve the pathological phenotype, yet the effectiveness depends on the type of mutations affecting the coenzyme Q$_{10}$ biosynthetic pathway (1, 26). Early treatment with pharmacological doses of coenzyme Q$_{10}$ is essential to limit irreversible organ damage in coenzyme Q$_{10}$-responsive deficiencies (1).

It is not clear to what extent coenzyme Q$_{10}$ supplementation might have therapeutic benefit in patients with inherited secondary Q$_{10}$ deficiencies. For example, multiple acyl-CoA dehydrogenase deficiency (MADD), caused by mutations in genes that impair the activity of enzymes involved in the transfer of electrons from acyl-CoA to coenzyme Q$_{10}$, is usually responsive to riboflavin monotherapy yet patients with low coenzyme Q$_{10}$ concentrations might also benefit from co-supplementation with coenzyme Q$_{10}$ and riboflavin (27). Another study suggested clinical improvements in secondary coenzyme Q$_{10}$ deficiency with supplemental coenzyme Q$_{10}$ in patients presenting with ataxia (28). Because the cause of secondary coenzyme Q$_{10}$ in inherited conditions is generally unknown, it is difficult to predict whether improving coenzyme Q$_{10}$ status with supplemental coenzyme Q$_{10}$ would lead to clinical benefits for the patients.

Finally, coenzyme Q$_{10}$ deficiency can be secondary to the inhibition of HMG-CoA reductase by statin drugs (see Deficiency). A 2015 meta-analysis of six small, randomized controlled trials found no reduction in statin-induced muscle pain with 100 to 400 mg/day of supplemental coenzyme Q$_{10}$ for one to three months (29). The trials failed to establish a diagnosis of relative coenzyme Q$_{10}$ deficiency before the intervention started, hence limiting the conclusion of the meta-analysis. While statin therapy may not necessary lead to a reduction in circulating coenzyme Q$_{10}$ concentrations, further research needs to examine whether secondary coenzyme Q$_{10}$ deficiency might be predisposing patients to statin-induced myalgia (30).

Cardiovascular disease

Congestive heart failure

Impairment of the heart's ability to pump enough blood for all of the body's needs is known as congestive heart failure. In coronary heart disease (CHD), accumulation of atherosclerotic plaque in the coronary arteries may prevent parts of the cardiac muscle from getting adequate blood supply, ultimately resulting in heart damage and impaired pumping ability. Heart failure can also be caused by myocardial infarction, hypertension, diseases of the heart valves, cardiomyopathy, and congenital heart diseases. Because physical exercise increases the demand on the weakened heart, measures of exercise tolerance are frequently used to monitor the severity of heart failure. Echocardiography is also used to determine the left ventricular ejection fraction, an objective measure of the heart's pumping ability (31).

A study of 1,191 heart failure patients found that low plasma coenzyme Q$_{10}$ concentration was a good biomarker of advanced heart disease (32). A number of small intervention trials that administered supplemental coenzyme Q$_{10}$ to congestive heart failure patients have been conducted. A 2014 literature review identified seven small randomized controlled trials examining the effect of coenzyme Q$_{10}$ supplementation (60-200 mg/day for ≤3 months in most trials) in heart failure patients (33). Pooling data from some of the trials showed an increase in serum coenzyme Q$_{10}$ concentrations (three studies) but no effect on left ventricular ejection fraction (two studies) or exercise capacity (two studies) (33). However, a recent meta-analysis of 14 randomized, placebo-controlled trials in 2,149 participants with heart failure found that supplemental coenzyme Q$_{10}$ (30-300 mg/day) resulted in a 39% reduction in mortality (seven studies), improved exercise capacity (four studies), but had no effect on left ventricular ejection fraction (nine studies) compared to placebo (34).

A trial is presently being conducted to assess the value of supplemental coenzyme Q$_{10}$ and/or D-ribose in the treatment of congestive heart failure in patients with normal left ventricular ejection fraction (35).

Ischemia-reperfusion injury

The heart muscle may become oxygen-deprived (ischemic) as the result of myocardial infarction or during cardiac surgery. Increased generation of reactive oxygen species (ROS) when the heart muscle's oxygen supply is restored (reperfusion) might be an important contributor to myocardial damage occurring during ischemia-reperfusion (36). Pretreatment of animals with coenzyme Q$_{10}$ has been found to preserve myocardial function following ischemia-reperfusion injury by increasing ATP concentration, enhancing antioxidant capacity and limiting oxidative damage, regulating autophagy, and reducing cardiomyocyte apoptosis (37). Another potential source of ischemia-reperfusion injury is aortic clamping during some types of cardiac surgery, such as coronary artery bypass graft (CABG) surgery. Early placebo-controlled trials found that coenzyme Q$_{10}$ pretreatment (60-300 mg/day for 7-14 days prior to surgery) provided some benefit in short-term outcome measures after CABG surgery (38, 39). In a small randomized controlled trial in 30 patients, oral administration of coenzyme Q$_{10}$ for 7 to 10 days before CABG surgery reduced the need for mediastinal drainage, platelet transfusion, and positive inotropic drugs (e.g. dopamine) and the risk of arrhythmia within 24 hours post-surgery (40). In one trial that did not find preoperative coenzyme Q$_{10}$ supplementation to be of benefit, patients were treated with 600 mg of coenzyme Q$_{10}$ 12 hours prior to surgery (41), suggesting that preoperative coenzyme Q$_{10}$ treatment may need to commence at least one week prior to CABG surgery to improve surgical outcomes. The combined administration of coenzyme Q$_{10}$, lipoic acid, omega-3 fatty acids, magnesium orotate, and selenium at least two weeks before CABG surgery and four weeks after was examined in a randomized, placebo-controlled trial in 117 patients with heart failure (42). The treatment resulted in lower concentration of troponin-I (a marker of cardiac injury), shorter length of hospital stay, and reduced risk of postoperative transient cardiac dysfunction compared to placebo (42).

Although trials have included relatively few people and examined mostly short-term, post-surgical outcomes, the results are promising (43).

Periprocedural myocardial injury

Coronary angioplasty (also called percutaneous coronary intervention) is a nonsurgical procedure for treating obstructive coronary heart disease, including unstable angina pectoris, acute myocardial infarction, and multivessel coronary heart disease. Angioplasty involves temporarily inserting and inflating a tiny balloon into the clogged artery to help restore the blood flow to the heart. Periprocedural myocardial injury that occurs in up to one-third of patients undergoing otherwise uncomplicated angioplasty increases the risk of morbidity and mortality at follow-up.

A prospective cohort study followed 55 patients with acute ST segment elevation myocardial infarction (a type of heart attack characterized by the death of some myocardial tissue) who underwent angioplasty (44). Plasma coenzyme Q$_{10}$ concentration one month after angioplasty was positively correlated with less inflammation and oxidative stress and predicted favorable left ventricular end-systolic volume remodeling at six months (44). One randomized controlled trial has examined the effect of coenzyme Q$_{10}$ supplementation on periprocedural myocardial injury in patients undergoing coronary angioplasty (45). The administration of 300 mg of coenzyme Q$_{10}$ 12 hours before the angioplasty to 50 patients reduced the concentration of C-reactive protein ([CRP]; a marker of inflammation) within 24 hours following the procedure compared to placebo. However, there was no difference in concentrations of two markers of myocardial injury (creatine kinase and troponin-I) or in the incidence of major adverse cardiac events one month after angioplasty between active treatment and placebo (45). Additional trials are needed to examine whether coenzyme Q$_{10}$ therapy can improve clinical outcomes in patients undergoing coronary angioplasty.

Angina pectoris

Myocardial ischemia may also lead to chest pain known as angina pectoris. People with angina pectoris often experience symptoms when the demand for oxygen exceeds the capacity of the coronary circulation to deliver it to the heart muscle, e.g., during exercise. Five small placebo-controlled studies have examined the effects of oral coenzyme Q$_{10}$ supplementation (60-600 mg/day) in addition to conventional medical therapy in patients with chronic stable angina (46). In most of the studies, coenzyme Q$_{10}$ supplementation improved exercise tolerance and reduced or delayed electrocardiographic changes associated with myocardial ischemia compared to placebo. However, only two of the studies found significant decreases in symptom frequency and use of nitroglycerin with coenzyme Q$_{10}$ supplementation. Presently, there is only limited evidence suggesting that coenzyme Q$_{10}$ supplementation would be a useful adjunct to conventional angina therapy.

Hypertension

Very few high-quality trials have examined the potential therapeutic benefit of coenzyme Q$_{10}$ supplementation in the treatment of primary hypertension (47). A systematic review identified two small randomized, double-blind, placebo-controlled trials that found little evidence of a reduction in systolic or diastolic blood pressure following the administration of coenzyme Q$_{10}$ (100-200 mg/day) for three months (47). In contrast, a meta-analysis that used less stringent selection criteria included 17 small trials and found evidence of a blood pressure-lowering effect of coenzyme Q$_{10}$ in patients with cardiovascular disease or metabolic disorders (48). The effect of coenzyme Q$_{10}$ on blood pressure needs to be examined in large, well-designed clinical trials.

Cardiovascular risk factors

Endothelial dysfunction: Normally functioning vascular endothelium promotes blood vessel relaxation (vasodilation) when needed (for example, during exercise) and inhibits the formation of blood clots. Atherosclerosis is associated with impairment of vascular endothelial function, thereby compromising vasodilation and normal blood flow. Endothelium-dependent vasodilation is impaired in individuals with elevated serum cholesterol concentrations, as well as in patients with coronary heart disease or diabetes mellitus. A 2012 meta-analysis examining the results of five small randomized controlled trials in 194 subjects in total found that supplemental coenzyme Q$_{10}$ (150-300 mg/day for 4 to 12 weeks) resulted in a clinically significant, 1.7% increase in flow-dependent endothelial-mediated dilation (49). Evidence from larger studies is needed to further establish the effect of coenzyme Q$_{10}$ on endothelium-dependent vasodilation.

Inflammation: Several small randomized controlled trials in patients at increased cardiovascular disease risk or with established cardiovascular disease have examined the effect of supplemental coenzyme Q$_{10}$ for ≤3 months on circulating inflammation markers i.e., CRP, interleukin-6, and/or tumor necrosis factor-α. Recently published pooled analyses of these trials have given mixed results (50-52). Larger studies are needed to examine the effect of coenzyme Q$_{10}$ supplementation on low-grade inflammation.

Blood lipids: Elevated plasma lipoprotein(a) concentration is an independent risk factor for cardiovascular disease. A meta-analysis of six controlled trials (of which five were randomized) in 409 participants found a reduction in plasma lipoprotein(a) concentration with coenzyme Q$_{10}$ supplementation (100-300 mg/day for 4-12 weeks) (53). Other effects of coenzyme Q$_{10}$ on blood lipids have not been reported (51, 53, 54).

A therapeutic approach combining coenzyme Q$_{10}$ with other antioxidants might prove to be more effective to target co-existing metabolic disorders in individuals at risk for cardiovascular disease (55).

Diabetes mellitus

Diabetes mellitus is a condition of increased oxidative stress and impaired energy metabolism. Plasma concentrations of reduced coenzyme Q$_{10}$ (CoQ$_{10}$H$_2$) have been found to be lower in diabetic patients than healthy controls after normalization to plasma cholesterol concentrations (56, 57). Randomized controlled trials that examined the effect of coenzyme Q$_{10}$ supplementation found little evidence of benefits on glycemic control in patients with diabetes mellitus. A meta-analysis of six trials in participants with type 2 diabetes and one trial in participants with type 1 diabetes found that 100 to 200 mg/day of coenzyme Q$_{10}$ for three to six months lowered neither fasting plasma glucose nor levels of glycated hemoglobin ([HbA1c]; a measure of glycemic control). Maternally inherited diabetes mellitus-deafness syndrome (MIDD) is caused by a mutation in mitochondrial DNA, which is inherited exclusively from one's mother. MIDD accounts for less than 1% of all cases of diabetes. Some early evidence suggested that long-term coenzyme Q$_{10}$ supplementation (150 mg/day) may improve insulin secretion and prevent progressive hearing loss in these patients (58, 59).

Of note, the pathogenesis of type 2 diabetes mellitus involves the early onset of glucose intolerance and hyperinsulinemia associated with the progressive loss of tissue responsiveness to insulin. Recent experimental studies tied insulin resistance to a decrease in coenzyme Q$_{10}$ expression and showed that supplementation with coenzyme Q$_{10}$ could restore insulin sensitivity (7). Coenzyme Q$_{10}$ supplementation might thus be a more useful tool for the primary prevention of type 2 diabetes rather than for its management.

Neurodegenerative diseases

Parkinson's disease

Parkinson's disease is a degenerative neurological disorder characterized by tremors, muscular rigidity, and slow movements. It is estimated to affect approximately 1% of Americans over the age of 65. Mitochondrial dysfunction and oxidative damage in a part of the brain called the substantia nigra may play a role in the development of the disease (60). Decreased ratios of reduced-to-oxidized coenzyme Q$_{10}$ have been found in platelets of individuals with Parkinson's disease (61, 62). One study also found higher concentrations of oxidized coenzyme Q$_{10}$ in the cerebrospinal fluid of patients with untreated Parkinson's disease compared to healthy controls (63). Additionally, a study in postmortem Parkinson's disease patients found lower concentrations of total coenzyme Q$_{10}$ in the cortex region of the brain compared to age-matched controls, but no differences were seen in other brain areas, including the striatum, substantia nigra, and cerebellum (64).

A 16-month randomized, placebo-controlled phase II clinical trial evaluated the safety and efficacy of 300, 600, or 1,200 mg/day of coenzyme Q$_{10}$ in 80 people with early Parkinson's disease (65). Coenzyme Q$_{10}$ supplementation was well tolerated at all doses and resulted in a slower deterioration of function in Parkinson's disease patients in the group taking 1,200 mg/day. A phase III clinical trial was then designed to further examine the effect of high-dose coenzyme Q$_{10}$ (1,200-2,400 mg/day) and vitamin E (1,200 IU/day) supplementation on both motor and non-motor symptoms associated with Parkinson's disease. This trial was prematurely terminated because it was unlikely that such a treatment was effective in treating Parkinson's disease (66). A smaller placebo-controlled trial showed that oral administration of 300 mg/day of coenzyme Q$_{10}$ for 48 to 96 months moderately improved motor symptoms in treated patients (with Levodopa) with re-emerging symptoms but not in patients at an early stage of the disease (67). Two recent meta-analyses of randomized, placebo-controlled trials found no evidence that coenzyme Q$_{10}$ improved motor-related symptoms or delayed the progression of the disease when compared to placebo (68, 69).

Huntington's disease

Huntington's disease is an inherited neurodegenerative disorder characterized by selective degeneration of nerve cells known as striatal spiny neurons. Symptoms, such as movement disorders and impaired cognitive function, typically develop in the fourth decade of life and progressively deteriorate over time. Animal models indicate that impaired mitochondrial function and glutamate-mediated neurotoxicity may be involved in the pathology of Huntington's disease. Some, but not all, studies in mouse models of Huntington's disease have suggested that coenzyme Q$_{10}$ supplementation could improve motor performance, overall survival, and various hallmarks of Huntington's disease, i.e., brain atrophy, ventricular enlargement, and striatal neuronal atrophy (70, 71). Interestingly, co-administration of coenzyme Q$_{10}$ with remacemide (an NMDA receptor antagonist), the antibiotic minocycline, or creatine led to greater improvements in most biochemical and behavioral parameters (70-72).

To date, only two clinical trials have examined whether coenzyme Q$_{10}$ might be efficacious in human patients with Huntington's disease. A 30-month, randomized, placebo-controlled trial of coenzyme Q$_{10}$ (600 mg/day), remacemide, or both in 347 patients with early Huntington's disease found that neither coenzyme Q$_{10}$ nor remacemide significantly altered the decline in total functional capacity, although coenzyme Q$_{10}$ supplementation (with or without remacemide) resulted in a nonsignificant trend toward a slower decline (73). A 20-week pilot trial examined the safety and tolerability of increasing dosages of coenzyme Q$_{10}$ (1,200 mg/day, 2,400 mg/day, and 3,600 mg/day) in eight healthy subjects and in 20 patients with Huntington's disease; 22 of the subjects completed the study (74). All dosages were generally well tolerated, with gastrointestinal symptoms being the most frequently reported adverse effect. Blood concentrations of coenzyme Q$_{10}$ at the end of the study were maximized with the daily dose of 2,400 mg (74). This dose was tested in a multicenter phase III clinical trial in 609 participants with early-stage Huntington's disease. Participants were randomized to receive either 2,400 mg/day of coenzyme Q$_{10}$ or placebo for five years (75). The trial was prematurely halted because it appeared unlikely to demonstrate any health benefit in supplemented patients — about one-third of participants completed the trial at the time of study termination (75). Although coenzyme Q$_{10}$ is generally well tolerated, there is no evidence that supplementation can improve functional and cognitive symptoms in Huntington's disease patients.

Inherited ataxias

Friedreich's ataxia (FRDA): FRDA is an autosomal recessive neurodegenerative disease caused by mutations in the gene *FXN* that encodes for the mitochondrial protein, frataxin. Frataxin is needed for the making of iron-sulfur clusters (ISC). ISC-containing subunits are especially important for the mitochondrial respiratory chain and for the synthesis of heme-containing proteins (76). Frataxin deficiency is associated with imbalances in iron-sulfur containing proteins, mitochondrial respiratory chain dysfunction and lower ATP production, and accumulation of iron in the mitochondria, which increases oxidative stress and oxidative damage to macromolecules of the respiratory chain (77). Clinically, FRDA is a progressive disease characterized by ataxia, areflexia, speech disturbance (dysarthria), sensory loss, motor dysfunction, cardiomyopathy, diabetes, and scoliosis (77). A pilot study administering coenzyme Q$_{10}$ (200 mg/day) and vitamin E (2,100 IU/day) to 10 FDRA patients found that energy metabolism of cardiac and skeletal muscle was improved after only three months of therapy (78). Follow-up assessments at 47 months indicated that cardiac and skeletal muscle improvements were maintained and that FRDA patients showed significant increases in fractional shortening, a measure of cardiac function. Moreover, the therapy was effective at preventing the progressive decline of neurological function (79). Another study reported both coenzyme Q$_{10}$ and vitamin E deficiencies among FRDA patients and suggested that co-supplementation with both compounds, at doses as low as 30 mg/day of coenzyme Q$_{10}$ and 4 IU/day of vitamin E, might improve disease symptoms (80). Large-scale, randomized controlled trials are necessary to determine whether coenzyme Q$_{10}$, in conjunction with vitamin E, has therapeutic benefit in FRDA. At present, about one-half of patients use coenzyme Q$_{10}$ and vitamin E supplements despite the lack of proven therapeutic benefit (77).

Spinocerebellar ataxias (SCAs): SCAs are a group of rare autosomal dominant neurodegenerative diseases characterized by gait difficulty, loss of hand dexterity, dysarthria, and cognitive decline. SCA1, 2, 3, and 6 are the most common SCAs (81). *In vitro* coenzyme Q$_{10}$ treatment of forearm skin fibroblasts isolated from patients with SCA2 was found to reduce oxidative stress and normalize complex I and II-III activity of the mitochondrial respiratory chain (82). A multicenter prospective cohort study that followed 319 patients with SCAs (≥15 years) found no difference in the rate of disease progression over two years between those taking supplemental coenzyme Q$_{10}$ (median dose, 600 mg/day) and nonusers (81).

Cancer

Early interest in coenzyme Q$_{10}$ as a potential therapeutic agent in cancer was stimulated by an observational study that found that individuals with lung, pancreas, and especially breast cancer were more likely to have low plasma coenzyme Q$_{10}$ concentrations than healthy controls (83). Two randomized controlled trials have explored the effect of coenzyme Q$_{10}$ as an adjunct to conventional therapy for breast cancer. Supplementation with coenzyme Q$_{10}$ failed to improve measures of fatigue and quality of life in patients newly diagnosed with breast cancer (84) and in patients receiving chemotherapy (85).

Performance

Athletic performance

There is little evidence that supplementation with coenzyme Q$_{10}$ improves athletic performance in healthy individuals. A few placebo-controlled trials have examined the effects of 100 to 150 mg/day of supplemental coenzyme Q$_{10}$ for three to eight weeks on physical performance in trained and untrained men. Most did not find significant differences between the group taking coenzyme Q$_{10}$ and the group taking placebo with respect to measures of aerobic exercise performance, such as maximal oxygen consumption (VO$_2$ max) and exercise time to exhaustion (86-90). One study found the maximal cycling workload to be slightly (4%) increased after eight weeks of coenzyme Q$_{10}$ supplementation compared to placebo, although measures of aerobic power were not increased (91). Two studies actually found significantly greater improvement in measures of anaerobic (87) and aerobic (86) exercise performance with a placebo than with supplemental coenzyme Q$_{10}$. More recent studies have suggested that coenzyme Q$_{10}$ could help reduce both muscle damage-associated oxidative stress and low-grade inflammation induced by strenuous exercise (92-95). Studies on the effect of supplementation on physical performance in women are lacking, but there is little reason to suspect a gender difference in the response to coenzyme Q$_{10}$ supplementation.

Sources

Biosynthesis

Coenzyme Q$_{10}$ is synthesized in most human tissues. The biosynthesis of coenzyme Q$_{10}$ involves three major steps: (1) synthesis of the benzoquinone structure from 4-hydroxybenzoate derived from either tyrosine or phenylalanine, two amino acids; (2) synthesis of the polyisoprenoid side chain from acetyl-coenzyme A (CoA) via the mevalonate pathway; and (3) the joining (condensation) of these two structures to form coenzyme Q$_{10}$. In the mevalonate pathway, the enzyme 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase, which converts HMG-CoA into mevalonate, is common to the biosynthetic pathways of both coenzyme Q$_{10}$ and cholesterol and is inhibited by statins (cholesterol-lowering drugs; see Drug interactions) (1).

Of note, pantothenic acid (formerly vitamin B$_5$) is the precursor of coenzyme A, and pyridoxine (vitamin B$_6$), in the form of pyridoxal-5'-phosphate, is required for the conversion of tyrosine to 4-hydroxyphenylpyruvic acid that constitutes the first step in the biosynthesis of the benzoquinone structure of coenzyme Q$_{10}$. It is not known to what extent the coenzyme Q$_{10}$ biosynthetic pathway may be affected by inadequate pantothenic acid and/or vitamin B$_6$ nutritional status.

Food sources

It has been estimated that dietary consumption contributes to about 25% of plasma coenzyme Q$_{10}$, but there are currently no specific dietary intake recommendations for coenzyme Q$_{10}$ from the US National Academy of Medicine (formerly the Institute of Medicine) or other agencies (96). The extent to which dietary consumption contributes to tissue coenzyme Q$_{10}$ concentrations is not clear.

Based on studies employing food frequency questionnaires, the average dietary intake of coenzyme Q$_{10}$ is about 3 to 6 mg/day (97). Rich sources of dietary coenzyme Q$_{10}$ include mainly meat, poultry, and fish. Other good sources include soybean, corn, olive, and canola oils; nuts; and seeds. Fruit, vegetables, eggs, and dairy products are moderate sources of coenzyme Q$_{10}$ (97). Some dietary sources are listed in **Table 1**.

Table 1. Coenzyme Q$_{10}$ Content of Selected Foods (98-100)

Food	Serving	Coenzyme Q$_{10}$ (mg)
Beef, fried	3 ounces*	2.6
Herring, marinated	3 ounces	2.3
Chicken, fried	3 ounces	1.4
Soybean oil	1 tablespoon	1.3
Canola oil	1 tablespoon	1.0
Rainbow trout, steamed	3 ounces	0.9
Peanuts, roasted	1 ounce	0.8
Sesame seeds, roasted	1 ounce	0.7
Pistachio nuts, roasted	1 ounce	0.6
Broccoli, boiled	½ cup, chopped	0.5
Cauliflower, boiled	½ cup, chopped	0.4
Orange	1 medium	0.3
Strawberries	½ cup	0.1
Egg, boiled	1 medium	0.1
*A three-ounce serving of meat or fish is about the size of a deck of cards.		

Supplements

Coenzyme Q$_{10}$ is available without a prescription as a dietary supplement in the US. Doses in supplements for adults range from 30 to 100 mg/day, which are considerably higher than typically estimated dietary coenzyme Q$_{10}$ intakes. Coenzyme Q$_{10}$ is fat-soluble and is best absorbed with fat in a meal. Doses higher than 100 mg/day are generally divided into two or three doses throughout the day (101). Less than 5% of orally administered coenzyme Q$_{10}$ is thought to reach the circulation (102). Therefore, pharmacological doses of coenzyme Q$_{10}$ as high as 1,200 to 3,000 mg/day for adults and 30 mg/kg/day for children are usually needed to relieve symptoms in patients with coenzyme Q$_{10}$ deficiency (26).

Does oral coenzyme Q$_{10}$ supplementation increase tissue concentrations?

Oral supplementation with coenzyme Q$_{10}$ is known to increase blood and lipoprotein concentrations of coenzyme Q$_{10}$ in humans (2, 15, 22). Plasma coenzyme Q$_{10}$ appears to reach a plateau following supplementation with a dose of 2,400 mg/day (103, 104). Yet, under normal circumstances, uptake of supplemental coenzyme Q$_{10}$ from peripheral tissues/organs is likely limited because coenzyme Q$_{10}$ is ubiquitously synthesized (105). Nonetheless, under certain physiological circumstances (e.g., aging) or in pathologies, coenzyme Q$_{10}$ status might be compromised and it is then presumed that supplementation might increase coenzyme Q$_{10}$ concentrations in tissues that are deficient (106). For example, a study in 24 older adults supplemented with 300 mg/day of coenzyme Q$_{10}$ or placebo for at least seven days prior to cardiac surgery found that the coenzyme Q$_{10}$ content of atrial tissue was significantly increased in those taking coenzyme Q$_{10}$, especially in patients greater than 70 years of age (38). In another study of patients with left ventricular dysfunction, supplementation with 150 mg/day of coenzyme Q$_{10}$ for four weeks before cardiac surgery increased coenzyme Q$_{10}$ concentrations in the heart but not in skeletal muscle (107). Finally, a 2007 review of the literature highlighted that plasma coenzyme Q$_{10}$ concentrations higher than 'normal' were likely needed to promote coenzyme Q$_{10}$ uptake by peripheral tissues and different tissues may indeed require different plasma thresholds for the uptake of coenzyme Q$_{10}$ (102).

Safety

Toxicity

There have been no reports of significant adverse side effects of oral coenzyme Q$_{10}$ supplementation at doses as high as 3,000 mg/day for up to eight months (103), 1,200 mg/day for up to 16 months (65), and 600 mg/day for up to 30 months (73). According to the observed safe level (OSL) risk assessment method, evidence of safety is strong with doses up to 1,200 mg/day of coenzyme Q$_{10}$ (108). Some people have experienced gastrointestinal symptoms, such as nausea, diarrhea, appetite suppression, heartburn, and abdominal discomfort, especially with daily doses ≥200 mg (109). These adverse effects may be minimized if daily doses >100 mg are divided into two or three daily doses (101). During pregnancy, the use of coenzyme Q$_{10}$ supplements (100 mg twice daily) from 20 weeks' gestation was found to be safe (110). Because reliable data in lactating women are not available, supplementation should be avoided during breast-feeding (110).

Drug interactions

Warfarin

Concomitant use of warfarin (Coumadin) and coenzyme Q$_{10}$ supplements has been reported to decrease the anticoagulant effect of warfarin in a few cases (111). An individual on warfarin should not begin taking coenzyme Q$_{10}$ supplements without consulting the health care provider who is managing his or her anticoagulant therapy. If warfarin and coenzyme Q$_{10}$ are to be used concomitantly, blood tests to assess clotting time (prothrombin time; PT/INR) should be monitored frequently, especially in the first two weeks.

HMG-CoA reductase inhibitors (statins)

HMG-CoA reductase is an enzyme that catalyzes a biochemical reaction that is common to both cholesterol and coenzyme Q$_{10}$ biosynthetic pathways (see Biosynthesis). Statins are HMG-CoA reductase inhibitors that are widely used as cholesterol-lowering medications. Statins can thus also reduce the endogenous synthesis of coenzyme Q$_{10}$. Therapeutic use of statins, including simvastatin (Zocor), pravastatin (Pravachol), lovastatin (Mevacor, Altocor, Altoprev), rosuvastatin (Crestor), and atorvastatin (Lipitor), has been shown to decrease circulating coenzyme Q$_{10}$ concentrations (112-121). However, because coenzyme Q$_{10}$ circulates with lipoproteins, plasma coenzyme Q$_{10}$ concentration is influenced by the concentration of circulating lipids (122, 123). It is likely that circulating coenzyme Q$_{10}$ concentrations are decreased because statins reduce circulating lipids rather than because they inhibit coenzyme Q$_{10}$ synthesis (124). In addition, very few studies have examined coenzyme Q$_{10}$ concentrations in tissues other than blood such that the extent to which statin therapy affects coenzyme Q$_{10}$ concentrations in the body's tissues is unknown (118, 120, 125). Finally, there is currently little evidence to suggest that secondary coenzyme Q$_{10}$ deficiency is responsible for statin-associated muscle symptoms in treated patients. In addition, supplementation with coenzyme Q$_{10}$ failed to relieve myalgia in statin-treated patients (see Disease Treatment) (126, 127).

Summary

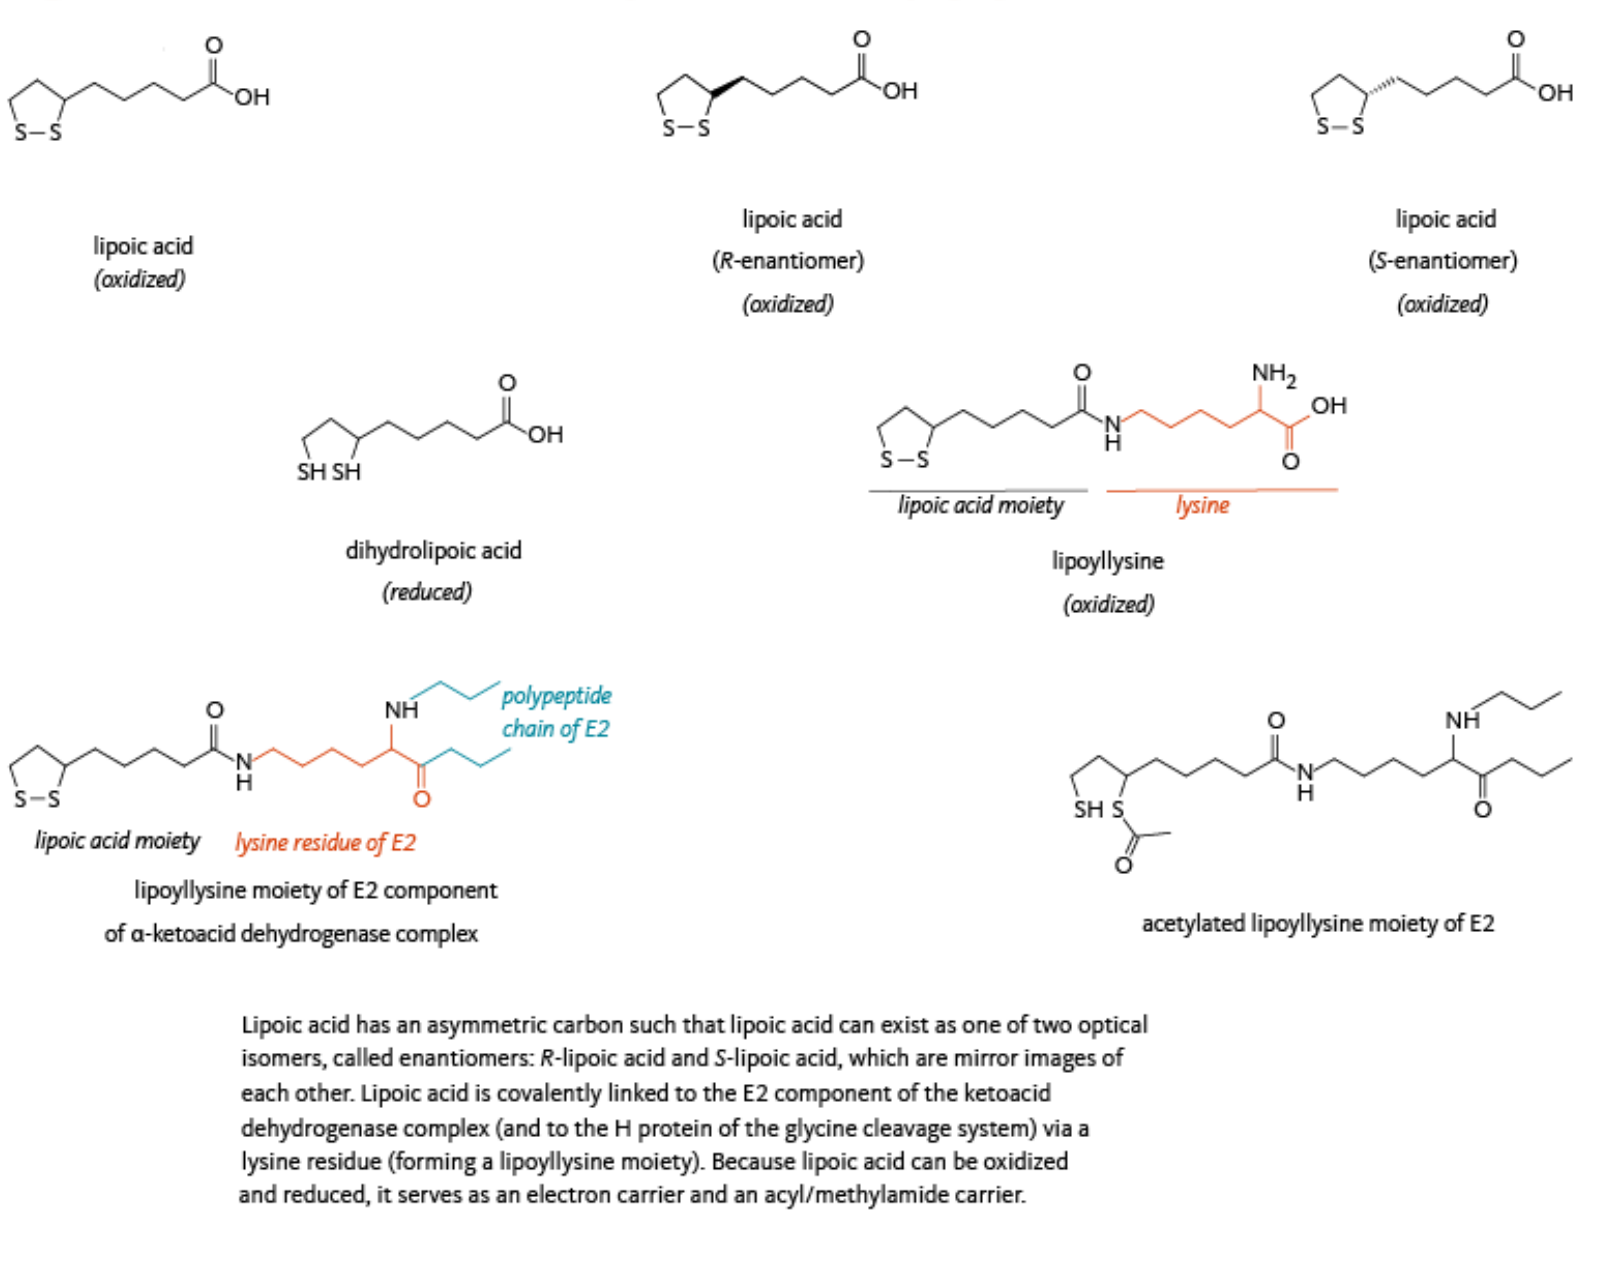
- Lipoic acid (often called α-lipoic acid), also known as thioctic acid, is a naturally occurring compound that is also synthesized by humans. (More information)
- Endogenously synthesized lipoic acid is bound to protein and functions as a cofactor for several important mitochondrial multienzyme complexes. (More information)
- Supplementation with lipoic acid transiently increases plasma and cellular concentrations of unbound lipoic acid. (More information)
- Lipoic acid is a direct antioxidant, although any increase in radical scavenging activity *in vivo* is likely transient. Lipoic acid may also trigger antioxidant defense, enhance cellular glucose uptake, and modulate the activity of various cell-signaling molecules and transcription factors. (More information)
- Some evidence from small randomized controlled studies suggests that high-dose lipoic acid may improve measures of glucose utilization in subjects with metabolic disorders. (More information)
- Available evidence suggests that treatment with intravenous or oral lipoic acid may help reduce symptoms of diabetic peripheral neuropathy. It is important to note that many of the studies examining the efficacy of lipoic acid for the treatment of diabetic neuropathy have been conducted by one German research group and funded by the manufacturer of lipoic acid in Germany. (More information)
- Lipoic acid was found to slow disease progression when administered to a mouse model of multiple sclerosis. A two-year clinical trial designed to assess the effect of lipoic acid on loss of mobility and changes in brain volume in patients with progressive multiple sclerosis is ongoing. (More information)
- Current evidence is too limited to suggest whether lipoic acid supplementation could benefit patients with Alzheimer's disease. (More information)
- Supplementation with lipoic acid may show some benefits in terms of weight control for individuals with high body mass index. (More information)
- Lipoic acid occurs naturally in food covalently bound to protein, whereas supplements contain unbound (free) lipoic acid. If you choose to use supplements, the Linus Pauling Institute recommends a daily dose of 200 to 400 mg/day for generally healthy people. (More information)

Introduction

Lipoic acid (often called α-lipoic acid), also known as thioctic acid, is a naturally occurring organosulfur compound that is synthesized by plants and animals, including humans (1, 2). Lipoic acid is covalently bound to certain proteins, which function as part of essential mitochondrial multienzyme complexes involved in energy and amino acid metabolism (see Biological Activities). In addition to the physiological functions of protein-bound lipoic acid, there is increasing scientific and medical interest in potential therapeutic uses of pharmacological doses of free (unbound) lipoic acid (3).

Lipoic acid contains two thiol (sulfur) groups, which may be oxidized or reduced; dihydrolipoic acid is the reduced form of lipoic acid (**Figure 1**) (4). Lipoic acid also contains an asymmetric carbon, which means that lipoic acid can exist as one of two possible optical isomers, also called enantiomers. These enantiomers are mirror images of each other: *R*-lipoic acid and *S*-lipoic acid (**Figure 1**). Only the *R*-enantiomer is endogenously synthesized and covalently bound to protein. *R*-lipoic acid occurs naturally in food (see Food sources). Free (unbound) lipoic acid supplements may contain either *R*-lipoic acid or a 50:50 (racemic) mixture of *R*-lipoic acid and *S*-lipoic acid (see Supplements).

Figure 1. Chemical Structures of Lipoic Acid and Lipoyllysine Residue



Lipoic acid has an asymmetric carbon such that lipoic acid can exist as one of two optical isomers, called enantiomers: *R*-lipoic acid and *S*-lipoic acid, which are mirror images of each other. Lipoic acid is covalently linked to the E2 component of the ketoacid dehydrogenase complex (and to the H protein of the glycine cleavage system) via a lysine residue (forming a lipoyllysine moiety). Because lipoic acid can be oxidized and reduced, it serves as an electron carrier and an acyl/methylamide carrier.

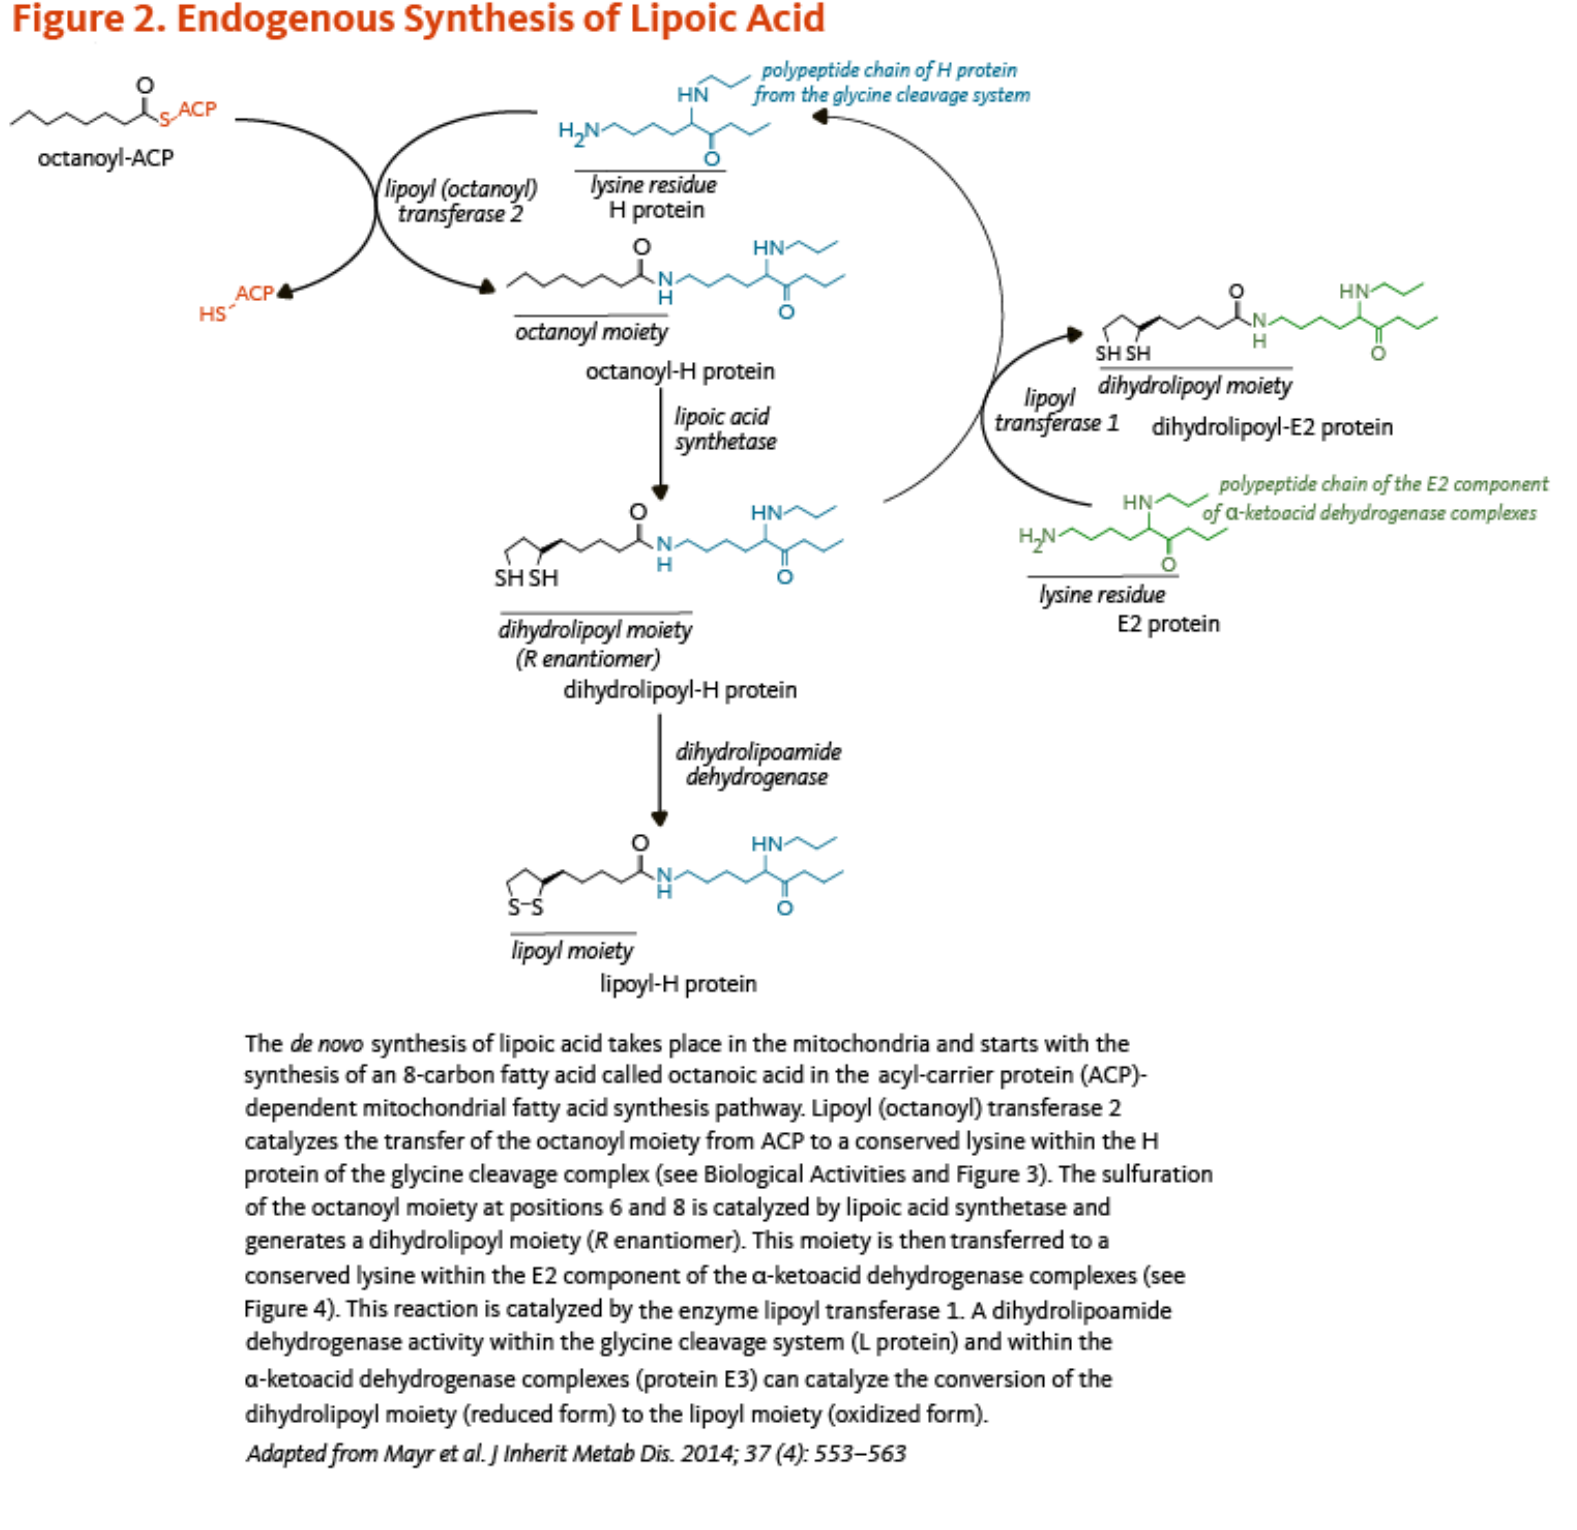
Metabolism and Bioavailability

Endogenous biosynthesis

The synthesis of lipoic acid has been characterized in detail in the yeast *Saccharomyces cerevisiae*, but not all genes involved in the process have been identified in humans (5). Lipoic acid is synthesized *de novo* in mitochondria from octanoic acid, an 8-carbon fatty acid (C8:0), bound to the acyl-carrier protein (ACP; see article on Pantothenic Acid) during the process of fatty acid synthesis (**Figure 2**). An enzyme called lipoyl (octanoyl) transferase 2 catalyzes the transfer of the octanoyl moiety from octanoyl-ACP to a conserved lysine of the H protein of the glycine cleavage system (see also Biological Activities). The next reaction is the insertion of two sulfur atoms at positions 6 and 8 of the protein H-bound octanoyl moiety, thereby producing a dihydrolipoyl moiety. This step is catalyzed by the lipoic acid synthetase (also called lipoyl synthase), an enzyme containing iron-sulfur clusters that act as sulfur donors in the reaction (5). Finally, the enzyme lipoyl transferase 1 catalyzes the transfer of the dihydrolipoyl moiety from the H protein of the glycine cleavage system to conserved lysine residues of the E2 components of the α-ketoacid dehydrogenase multienzyme complexes (5). The oxidation of the dihydrolipoyl moiety is catalyzed by a dihydrolipoamide dehydrogenase (**Figure 2**).

Figure 2. Endogenous Synthesis of Lipoic Acid



The *de novo* synthesis of lipoic acid takes place in the mitochondria and starts with the synthesis of an 8-carbon fatty acid called octanoic acid in the acyl-carrier protein (ACP)-dependent mitochondrial fatty acid synthesis pathway. Lipoyl (octanoyl) transferase 2 catalyzes the transfer of the octanoyl moiety from ACP to a conserved lysine within the H protein of the glycine cleavage complex (see Biological Activities and Figure 3). The sulfuration of the octanoyl moiety at positions 6 and 8 is catalyzed by lipoic acid synthetase and generates a dihydrolipoyl moiety (*R* enantiomer). This moiety is then transferred to a conserved lysine within the E2 component of the α-ketoacid dehydrogenase complexes (see Figure 4). This reaction is catalyzed by the enzyme lipoyl transferase 1. A dihydrolipoamide dehydrogenase activity within the glycine cleavage system (L protein) and within the α-ketoacid dehydrogenase complexes (protein E3) can catalyze the conversion of the dihydrolipoyl moiety (reduced form) to the lipoyl moiety (oxidized form).

Dietary and supplemental lipoic acid

Consumption of lipoic acid from food has not yet been found to result in detectable increases of free lipoic acid in human plasma or cells (3, 6). In contrast, high oral doses of free lipoic acid (≥50 mg) significantly, yet transiently, increase the concentration of free lipoic acid in plasma and cells. Pharmacokinetic studies in humans have found that about 30%-40% of an oral dose of a racemic mixture of *R*-lipoic acid and *S*-lipoic acid is absorbed (6, 7). Oral lipoic acid supplements are better absorbed on an empty stomach than with food: taking lipoic acid with food (versus without food) decreased peak plasma lipoic acid concentrations by about 30% and total plasma lipoic acid concentrations by about 20% (8). A liquid formulation of *R*-lipoic acid was found to be better absorbed and more stable in the plasma, suggesting that it might be more efficacious than the solid form in the management of a condition like diabetic neuropathy (9, 10).

There may also be differences in bioavailability of the two isomers of lipoic acid. Following single oral doses *R,S*-lipoic acid (racemic mixture), peak plasma concentrations of *R*-lipoic acid were found to be 40%-50% higher than *S*-lipoic acid, suggesting a differential absorption in favor of the *R*-enantiomer (6, 8, 11). Yet, following oral ingestion, both enantiomers are rapidly metabolized and excreted. Plasma lipoic acid concentrations generally peak within one hour or less and decline rapidly (6, 7, 11, 12). In cells, lipoic acid is swiftly reduced to dihydrolipoic acid, and *in vitro* studies indicate that dihydrolipoic acid is then rapidly exported from cells (3). Moreover, a pilot study in 19 healthy adults suggested that the bioavailability of *R,S*-lipoic acid and *R*-lipoic acid may vary with age and gender (13).

Finally, there is no evidence in humans that exogenous lipoic acid can be 'activated' with ATP or GTP and incorporated into lipoic acid-dependent enzymes by a lipoyl transferase (14). As a consequence, a loss of lipoic acid-dependent enzymatic activity caused by defects in endogenous lipoic acid synthesis (see Deficiency) cannot be rescued by the provision of exogenous lipoic acid (5).

Biological Activities

Protein-bound lipoic acid

Enzyme cofactor

R-lipoic acid is an essential cofactor for several mitochondrial multienzyme complexes that catalyze critical reactions related to the catabolism (breakdown) of amino acids and the production of energy (15). *R*-lipoic acid is covalently bound to a specific lysine residue in at least one of the proteins in each multienzyme complex. Such a non-protein cofactor is known as a "prosthetic group."

R-lipoic acid functions as a prosthetic group for the biological activity of the following multienzyme complexes:

- The **glycine cleavage system** that catalyzes the decarboxylation of glycine coupled with the addition of a methylene group (-CH_2) to tetrahydrofolate to form 5,10-methylene tetrahydrofolate, an important cofactor in the synthesis of nucleic acids (**Figure 3**). Within the glycine cleavage system, *R*-lipoic acid is covalently bound to a conserved lysine of the H protein (**Figures 2 and 3**).
- Four α-ketoacid dehydrogenase complexes (**Figure 4**), including:

(i) the **pyruvate dehydrogenase complex** that catalyzes the conversion of pyruvate to acetyl-coenzyme A (CoA), an important substrate for energy production via the citric acid cycle;

(ii) the **α-ketoglutarate dehydrogenase complex** that catalyzes the conversion of α-ketoglutarate to succinyl CoA, another important intermediate of the citric acid cycle;

(iii) the **branched-chain α-ketoacid dehydrogenase complex** that is involved in the decarboxylation of ketoacids in the catabolic pathway of the branched-chain amino acids, namely leucine, isoleucine, and valine;

(iv) the **2-oxoadipate dehydrogenase complex** that catalyzes the decarboxylation of 2-oxoadipate to glutaryl-CoA in the catabolic pathway of lysine, hydroxylysine, and tryptophan.

All four α-ketoacid dehydrogenase complexes contain three enzymatic activities, namely E1, E2, and E3. E1 is a thiamin pyrophosphate (TPP)-dependent α-ketoacid dehydrogenase, *R*-lipoic acid functions as a prosthetic group essential for E2 transacetylase activity, and E3 is a flavin adenine dinucleotide (FAD)-dependent dihydrolipoamide dehydrogenase (**Figure 4**). *R*-lipoic acid is also found in the E3-binding protein (protein X component) of the pyruvate dehydrogenase complex (5).

The glycine cleavage system is a multienzyme complex of four protein components: P, T, L, and H. The P protein catalyzes the decarboxylation of glycine and the transfer of the methylamine residue (CH_2- NH_2) of glycine to the lipoyl moiety of the H protein. The H protein shuttles the methylamine to the T protein. The latter then catalyzes the transfer of the methylene group (CH_2) to tetrahydrofolate. In the process, NH_3 is released and the lipoyl group of the H protein is reduced (dihydrolipoyl group). Finally, the L protein catalyzes the re-oxidation of the lipoyl moiety of the H protein in an NAD–dependent reaction.

The α-ketoacid dehydrogenase multienzyme complex family includes (1) the pyruvate dehydrogenase complex; (2) the branched-chain α-ketoacid dehydrogenase complex; (3) the α-ketoglutarate dehydrogenase complex; and (4) the 2-oxoadipate dehydrogenase complex, which all share the same architecture. Each complex is composed of several copies of three enzymes: E1, E2, and E3. E1 is a TPP-dependent α-ketoacid dehydrogenase; E2 is a dihydrolipoamide transacetylase; and E3 is an FAD-containing dihydrolipoamide dehydrogenase. The E2 unit binds one or two lipoyl groups via a covalent amide linkage to a lysine group. Each complex catalyzes the conversion of specific α-ketoacids into CO_2 and acyl-CoA.

Unbound lipoic acid

When considering the biological activities of supplemental (unbound) lipoic acid, it is important to keep in mind the limited and transient nature of the increases in plasma and tissue lipoic acid (see Metabolism and Bioavailability) (3).

Antioxidant activities

Scavenging reactive oxygen and nitrogen species: Reactive oxygen species (ROS) and reactive nitrogen species (RNS) are highly reactive compounds with the potential to damage DNA, proteins, and lipids in cell membranes. Both lipoic acid and dihydrolipoic acid can directly scavenge (neutralize) physiologically relevant ROS and RNS in the test tube (reviewed in 3). However, whether direct quenching reactions occur *in vivo* is unknown. The highest tissue concentrations of free lipoic acid likely to be achieved through oral supplementation are at least 10 times lower than those of other intracellular antioxidants, such as vitamin C and glutathione. Moreover, free lipoic acid is rapidly eliminated from cells, so any increases in direct radical scavenging activity are unlikely to be sustained.

Regeneration of other antioxidants: When an antioxidant scavenges a free radical, it becomes oxidized itself and is not able to scavenge additional ROS or RNS until it has been reduced. In the test tube, dihydrolipoic acid is a potent reducing agent with the capacity to reduce the oxidized forms of several important antioxidants, including coenzyme Q_{10}, vitamin C, and glutathione (**Figure 5**) (16, 17). Dihydrolipoic acid may also reduce the oxidized form of α-tocopherol (vitamin E) directly or indirectly through regenerating oxidized vitamin C (see the article on Vitamin E) (18) or oxidized coenzyme Q_{10} (see the article on Coenzyme Q_{10}) (19). Whether dihydrolipoic acid effectively regenerates antioxidants under physiological conditions is unclear (3).

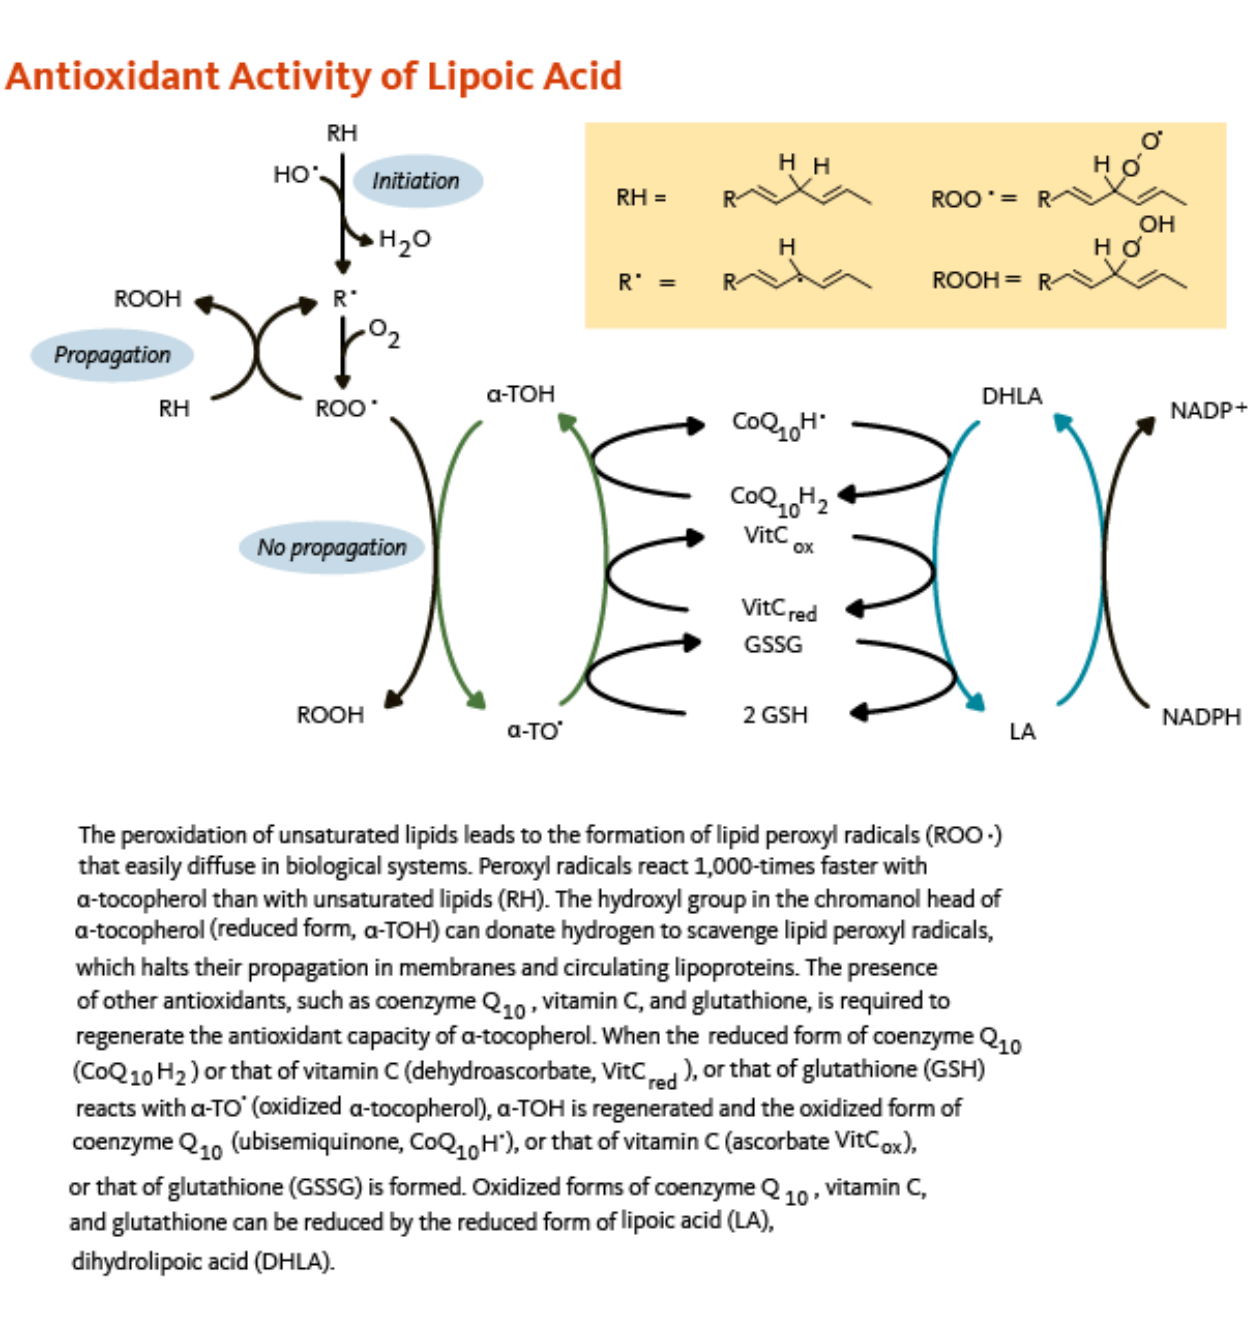
Metal chelation: Redox-active metal ions, such as free iron and copper, can induce oxidative damage by catalyzing reactions that generate highly reactive free radicals (20). Compounds that chelate free metal ions in a way that prevents them from generating free radicals offer promise in the treatment of neurodegenerative diseases and other chronic diseases in which metal-induced oxidative damage may play a pathogenic role (21). Both lipoic acid and dihydrolipoic acid have been found to inhibit copper- and iron-mediated oxidative damage in the test tube (22, 23) and to inhibit excess iron and copper accumulation in animal models (24, 25). Lipoic acid may also be helpful as an adjunct treatment against heavy metal toxicity. No clinical trial has examined the use of lipoic acid as a chelating agent in mercury toxicity, yet it has proven to be effective in several mammalian species (26, 27).

Activation of antioxidant signaling pathways: Glutathione is an important intracellular antioxidant that also plays a role in the detoxification and elimination of potential carcinogens and toxins. Reductions in glutathione synthesis and tissue glutathione concentrations in aged animals (compared to younger ones) are suggestive of a potentially lower ability to respond to oxidative stress or toxin exposure (28). Lipoic acid has been found to increase glutathione concentrations in cultured cells and in the tissues of aged animals fed lipoic acid (29, 30). Lipoic acid might be able to increase glutathione synthesis in aged rats by up-regulating the expression of γ-glutamylcysteine ligase (γ-GCL), the rate-limiting enzyme in glutathione synthesis (31), and by increasing cellular uptake of cysteine, an amino acid required for glutathione synthesis (32). Lipoic acid was found to upregulate the expression of γ-GCL and other antioxidant enzymes via the activation of the nuclear factor E2-related factor 2 (Nrf2)-dependent pathway (31, 33).

Briefly, Nrf2 is a transcription factor that is bound to the protein Kelch-like ECH-associated protein 1 (Keap1) in the cytosol. Keap1 responds to oxidative stress signals by freeing Nrf2. Upon release, Nrf2 translocates to the nucleus where it can bind to the antioxidant response element (ARE) located in the promoter region of genes coding for antioxidant enzymes and scavengers. Lipoic acid — but not dihydrolipoic acid — can react with specific sulfhydryl residues of Keap1, causing the release of Nrf2 (34). Nrf2/ARE target genes code for several mediators of the antioxidant response, including γ-GCL, NAD(P)H quinone oxidoreductase 1 (NQO-1), heme oxygenase-1 (HO-1), catalase, and superoxide dismutase (SOD). For example, the upregulation of the Nrf2 pathway by lipoic acid in cultured hepatocytes and in the liver of obese or diabetic rats prevented lipid overload-induced steatosis (35) and cell death (36). Lipoic acid also protected liver from oxidative stress-induced liver injury in methotrexate-treated rats through the activation of Nrf-2 pathway and other anti-inflammatory pathways (37). Pre-treatment and post-treatment with lipoic acid, respectively, prevented and reversed lipopolysaccharide (LPS)-induced lung histopathological alterations in rats through Nrf2-mediated HO-1 upregulation (38).

Inhibition of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase (NOX): NOX is a plasma membrane-bound enzymatic complex that catalyzes the production of superoxide from oxygen and NADPH and has been involved in innate immune defense against microbes (39). Lipoic acid prevented NOX-induced superoxide production in a rat model of cerebral ischemia and limited infarct volume and neurological deficiencies through upregulating the insulin-phosphatidylinositide-3 kinase (PI3K)-protein kinase B (PKB/Akt) signaling pathway (40). Treatment of gastric cancer cells with lipoic acid limited NOX-generated ROS production and reduced cancer cell proliferation induced by *Helicobacter pylori* (*H. pylori*) infection (41).

Figure 5. Antioxidant Activity of Lipoic Acid



The peroxidation of unsaturated lipids leads to the formation of lipid peroxyl radicals (ROO•) that easily diffuse in biological systems. Peroxyl radicals react 1,000-times faster with α-tocopherol than with unsaturated lipids (RH). The hydroxyl group in the chromanol head of α-tocopherol (reduced form, α-TOH) can donate hydrogen to scavenge lipid peroxyl radicals, which halts their propagation in membranes and circulating lipoproteins. The presence of other antioxidants, such as coenzyme Q_{10}, vitamin C, and glutathione, is required to regenerate the antioxidant capacity of α-tocopherol. When the reduced form of coenzyme Q_{10} ($CoQ_{10}H_2$) or that of vitamin C (dehydroascorbate, $VitC_{red}$), or that of glutathione (GSH) reacts with α-TO• (oxidized α-tocopherol), α-TOH is regenerated and the oxidized form of coenzyme Q_{10} (ubisemiquinone, $CoQ_{10}H^•$), or that of vitamin C (ascorbate $VitC_{ox}$), or that of glutathione (GSSG) is formed. Oxidized forms of coenzyme Q_{10}, vitamin C, and glutathione can be reduced by the reduced form of lipoic acid (LA), dihydrolipoic acid (DHLA).

[Figure 5 - Click to Enlarge]

Regulation of cellular glucose uptake

The binding of insulin to the insulin receptor stimulates a cascade of protein phosphorylations leading to the translocation of glucose transporters (GLUT4) to the cell membrane and an increased cellular uptake of glucose (3, 42). Lipoic acid has been found to activate the insulin signaling cascade in cultured cells (3, 42, 43), increase GLUT4 translocation to cell membranes, and increase glucose uptake in cultured adipose and muscle cells (44, 45). A computer modeling study suggested that lipoic acid might bind to the intracellular tyrosine kinase domain of the insulin receptor and stabilize the active form of the enzyme (43).

Regulation of other signaling pathways

In addition to Nrf2 and insulin signaling pathways, lipoic acid was found to target other cell-signaling molecules thereby affecting a variety of cellular processes, including metabolism, stress responses, proliferation, and survival. For example, in cultured endothelial cells, lipoic acid was found to inhibit IKK-β, an enzyme that promotes the translocation of redox-sensitive and pro-inflammatory transcription factor, nuclear factor-kappa B (NFκB) from the cytosol to the nucleus (46). Lipoic acid has also been shown to improve nitric oxide (NO)-dependent vasodilation in aged rats by increasing PKB/Akt-dependent phosphorylation of endothelial NO synthase (eNOS) and eNOS-catalyzed NO production (47). Additionally, lipoic acid increased mitochondrial biogenesis through triggering AMP-activated protein kinase (AMPK)-induced transcription factor PGC-1α activation in skeletal muscle of aged mice (48). Several reviews of the literature have described pathways that are potential targets of lipoic acid in various models and under different experimental conditions (49-52).

Deficiency

Lipoic acid deficiency has been described in rare cases of inherited mutations in the lipoic acid biosynthetic pathway. Mutations identified in patients with defective lipoic acid metabolism affect genes involved in the synthesis of iron-sulfur clusters and genes coding for lipoic acid synthetase (*LIAS*), lipoyl transferase 1 (*LIPT1*), and dihydrolipoamide dehydrogenase (E3 component of α-ketoacid dehydrogenase complexes; *DLD*) (5, 53, 54).

Disease Treatment

Diabetes mellitus

Chronically elevated blood glucose concentration is the hallmark of diabetes mellitus. Type 1 diabetes is caused by the autoimmune destruction of the insulin-producing β-cells of the pancreas, leading to an insufficient production of insulin. Exogenous insulin is required to maintain a normal blood glucose concentration (i.e., fasting blood glucose <100 milligram per deciliter [mg/dL]). In contrast, impaired tissue glucose uptake in response to insulin (a phenomenon called insulin resistance) plays a key role in the development of type 2 diabetes (55). Although patients with type 2 diabetes may eventually require insulin, interventions that enhance insulin sensitivity may be used to maintain normal blood glucose concentrations. The term 'prediabetes' is sometimes used to describe early metabolic abnormalities that place individuals at high risk of developing type 2 diabetes. Of note, these patients are also at high risk for cardiovascular disease. According to the American Diabetes Association, prediabetes can be defined by a condition of impaired fasting glucose, characterized by a fasting blood glucose concentration between 100 mg/dL and 125 mg/dL and/or a condition of impaired glucose tolerance, characterized by a 2-hour blood glucose concentration ≥140 mg/dL following an oral glucose tolerance test (56).

Glucose utilization

The effect of high-dose lipoic acid on glucose utilization has been primarily examined in individuals with type 2 diabetes. An early clinical trial in 13 patients with type 2 diabetes found that a single intravenous infusion of 1,000 mg of lipoic acid improved insulin-stimulated glucose disposal (i.e., insulin sensitivity) by 50% compared to a placebo infusion (57). A placebo-controlled study of 72 patients with type 2 diabetes found that oral administration of lipoic acid at doses of 600 mg/day, 1,200 mg/day or 1,800 mg/day improved insulin sensitivity by 25% after four weeks of treatment (58). There were no significant differences among the three doses of lipoic acid, suggesting that 600 mg/day may be the maximum effective dose (55). However, in a more recent randomized, placebo-controlled study in 102 subjects, daily supplementation with 600 mg of lipoic acid (+/- 800 mg of vitamin E [α-tocopherol]) for 16 weeks had no effect on fasting blood glucose, fasting blood insulin, or a measure of insulin resistance called the homeostatic model assessment of insulin resistance (HOMA-IR) index (59). A 2018 systematic review and meta-analysis identified 20 randomized controlled trials (published between 2007 and 2017) that examined the effect of supplemental lipoic acid on markers of glucose utilization in 1,245 subjects with metabolic disorders (not limited to type 2 diabetes) (60). Administration of lipoic acid (200 to 1,800 mg/day for 2 weeks to 1 year), alone or together with other nutrients, was found to lower fasting blood glucose and insulin concentrations, insulin resistance, and blood HbA1c concentration — a marker of glycemic control over the past few months (60).

Endothelial function

The inner lining of blood vessels, known as the vascular endothelium, plays an important role in the maintenance of cardiovascular health. In particular, nitric oxide (NO) regulates vascular tone and blood flow by promoting the relaxation of all types of blood vessels, including arteries — a phenomenon called vasodilation. Alterations in NO-mediated endothelium-dependent vasodilation results in widespread vasoconstriction and coagulation abnormalities and is considered to be an early step in the development of atherosclerosis. The presence of chronic hyperglycemia, insulin resistance, oxidative stress, and pro-inflammatory mechanisms contribute to endothelial dysfunction in patients with diabetes mellitus (61).

The measurement of brachial flow-mediated dilation (FMD) is often used as a surrogate marker of endothelial function. Two techniques are being used to measure endothelium-dependent vasodilation. One technique measures the forearm blood flow by venous occlusion plethysmography during infusion of acetylcholine. Using this invasive technique, intra-arterial infusion of lipoic acid was found to improve endothelium-dependent vasodilation in 39 subjects with type 2 diabetes but not in 11 healthy controls (62). A more recent randomized, double-blind, placebo-controlled study in 30 patients with type 2 diabetes found that intravenous infusion of 600 mg of lipoic acid improved the response to the endothelium-dependent vasodilator acetylcholine but not to the endothelium-independent vasodilator, glycerol trinitrate (63). Another noninvasive technique using ultrasound to measure flow-mediated vasodilation was used in two additional studies conducted by Xiang et al. (64, 65). The results of these randomized, placebo-controlled studies showed that intravenous lipoic acid could improve endothelial function in patients with impaired fasting glucose (64) or impaired glucose tolerance (65).

One randomized placebo-controlled trial that assessed the effect of oral lipoic acid supplementation in 58 patients diagnosed with metabolic syndrome, a condition characterized by abnormal glucose and lipid metabolism, showed that flow-mediated vasodilation improved by 44% with 300 mg/day of lipoic acid for four weeks (66).

Diabetic neuropathy

Peripheral neuropathy: Up to 50% of diabetic patients develop peripheral neuropathy, a type of nerve damage that may result in pain, loss of sensation, and weakness, particularly in the lower extremities (67). Peripheral neuropathy is also a leading cause of lower limb amputation in diabetic patients (68). Several mechanisms have been proposed to explain chronic hyperglycemia-induced nerve damage, such as intracellular accumulation of sorbitol, glycation reactions, and oxidative and nitrosative stress (reviewed in 69). The results of several large randomized controlled trials indicated that maintaining blood glucose at near normal concentrations was the most important step in limiting the risk of diabetic neuropathy and lower extremity amputation (70-72). However, evidence of the efficacy of enhanced control of glycemia in preventing neuropathy is stronger in patients with type 1 diabetes than in those with type 2 diabetes (73). Moreover, this glucose control intervention increased the risk of hypoglycemic episodes (73).

The efficacy of lipoic acid, administered either intravenously or orally, in the management of neuropathic symptoms has been examined in patients with diabetes. Meta-analyses of randomized controlled trials suggest that infusion of 300 to 600 mg/day of lipoic acid for two to four weeks significantly reduced the symptoms of diabetic neuropathy to a clinically meaningful degree (55, 74). Regarding the efficacy of oral lipoic acid supplementation, an initial short-term study in 24 patients with type 2 diabetes mellitus found that the symptoms of peripheral neuropathy improved in those who took 600 mg of lipoic acid three times a day for three weeks compared to those who took a placebo (75). A larger clinical trial randomly assigned more than 500 patients with type 2 diabetes and symptomatic peripheral neuropathy to one of the following treatments: (i) 600 mg/day of intravenous lipoic acid for three weeks followed by 1,800 mg/day of oral lipoic acid for six months, (ii) 600 mg/day of intravenous lipoic acid for three weeks followed by oral placebo for six months, or (iii) intravenous placebo for three weeks followed by oral placebo for six months (76). Evidence of improvements in sensory and motor deficits — assessed by physicians — could be observed after three weeks of intravenous lipoic acid therapy, yet not at the end of six months of oral lipoic acid therapy. However, another randomized, double-blind, placebo-controlled trial in 181 patients with diabetic neuropathy found that oral supplementation with either 600 mg/day, 1,200 mg/day, or 1,800 mg/day of lipoic acid for five weeks significantly improved neuropathic symptoms (77). In this study, the 600 mg/day dose was as effective as the higher doses. Finally, a four-year, multicenter, clinical trial in 421 diabetic patients with distal symmetric sensorimotor polyneuropathy found no difference between oral administration of 600 mg/day of lipoic and placebo on the primary endpoint, a composite score that assessed neuropathic impairment of the lower limbs and nerve conduction (78). Yet, measures of specific neuropathic impairments (secondary outcomes) improved with lipoic acid supplementation (78). A post-hoc analysis suggested that oral lipoic acid supplementation may reduce neuropathic symptoms particularly in subjects with a high burden of cardiovascular disease, diabetes, and neuropathy yet with normal body mass index (BMI) and blood pressure (79).

Autonomic neuropathy: Another neuropathic complication of diabetes mellitus is cardiac autonomic neuropathy (CAN), which occurs in as many as 25% of diabetic patients (55). CAN is characterized by damage to the nerve fibers that innervate the heart and blood vessels, leading to reduced heart rate variability (variability in the time interval between heartbeats) and increased risk of mortality (80). In a randomized controlled trial of 72 patients with type 2 diabetes and reduced heart rate variability, oral supplementation with 800 mg/day of lipoic acid for four months resulted in significant improvement in two out of four measures of heart rate variability compared to placebo (81).

Summary: Overall, the available research suggests that treatment with intravenous or oral lipoic acid may help reduce symptoms of diabetic peripheral neuropathy. The use of lipoic acid is currently approved for the treatment of diabetic neuropathy in Germany (4). It is important to note that many of the studies that examined the efficacy of lipoic acid in the treatment of diabetic neuropathy have been primarily conducted by one German research group and funded by the manufacturer of lipoic acid in Germany (82).

Diabetic retinopathy

Chronic hyperglycemia can damage blood vessels in the retina and cause a potentially sight-threatening condition called diabetic retinopathy (83). One placebo-controlled study examined the effect of lipoic acid on the visual capability of 80 participants of whom 12 had type 1 diabetes, 48 had type 2 diabetes, and 20 were diabetes-free. The result showed that daily oral administration of 300 mg of lipoic acid for three months prevented the deterioration of contrast sensitivity in patients with diabetes and improved it in healthy patients compared to placebo (84).

Multiple sclerosis

Multiple sclerosis is an autoimmune disease of unknown etiology that is characterized by the progressive destruction of myelin and nerve fibers in the central nervous system, causing neurological symptoms in affected individuals (85). There are four main types of multiple sclerosis defined according to the disease course: (i) clinically isolated syndrome, (ii) relapsing-remitting multiple sclerosis, (iii) secondary progressive multiple sclerosis, and (iv) primary progressive multiple sclerosis (for more information, visit the National Multiple Sclerosis Society website) (86). Lipoic acid was found to effectively slow disease progression when administered either orally (87), intraperitoneally (88), or subcutaneously (89) to mice with experimental autoimmune encephalomyelitis (EAE), a model of multiple sclerosis. *In vitro* and animal studies have found that lipoic acid exhibits immunomodulatory properties through mechanisms that stimulate the production of cyclic AMP (cAMP) (90, 91) — a central regulator of innate immune functions — and inhibits the migration of immune cells into the brain and spinal cord (92), possibly by decreasing endothelial expression of cell adhesion molecules, inhibiting expression of enzymes like matrix metalloproteinases (MMP), and/or reducing the permeability of the blood-brain barrier (87, 89, 93, 94).

Only a few studies have examined lipoic acid supplementation in humans. A small pilot study designed to evaluate the safety of lipoic acid in 30 people with relapsing or progressive multiple sclerosis found that treatment with 1,200 to 2,400 mg/day of oral lipoic acid for two weeks was generally well tolerated (see Safety) (95). In this study, higher serum concentrations of lipoic acid were associated with the lowest serum concentrations of MMP-9 — a marker of inflammation (95). Another study suggested that an oral dose of 1,200 mg of lipoic acid in subjects with multiple sclerosis could help achieve serum lipoic acid concentrations similar to those found to be therapeutic in mice (96). A randomized, placebo-controlled study in 52 subjects (mean age, 30 years) with relapsing-remitting multiple sclerosis found an increase in total antioxidant capacity in blood with lipoic acid supplementation (1,200 mg/day for 12 weeks) yet not in the activity of specific antioxidant enzymes (superoxide dismutase and glutathione peroxidase) (97). Supplemental lipoic acid also decreased the serum concentrations of some (IFN-γ, ICAM-1, TGF-γ, IL-4), but not all markers (TNF-γ, IL-6, MMP-9), cytokines and other inflammation (98). In addition, lipoic acid supplementation did not reduce the severity of multiple sclerosis symptoms, as assessed by the Expanded Disability Status Scale (EDSS) scoring system (98, 99).

A two-year clinical trial designed to assess the effect of lipoic acid (1,200 mg/day) on loss of mobility and changes in brain volume in patients with progressive multiple sclerosis is ongoing (85).

Cognitive impairments and dementia

Studies in animal models of aging and neurodegenerative disease have indicated that lipoic acid administration might improve measures of spatial memory, learning capacity, and/or motor function (reviewed in 100).

It is not known whether oral lipoic acid supplementation can slow cognitive decline related to aging or pathological conditions in humans. An uncontrolled, open-label trial in nine patients with probable Alzheimer's disease and related dementias, who were also taking acetylcholinesterase inhibitors, reported that oral supplementation with 600 mg/day of lipoic acid appeared to stabilize cognitive function over a one-year period (101). A subsequent study that followed 43 patients for up to four years found those with mild dementia or moderate-early dementia who took lipoic acid (600 mg/day), in addition to acetylcholinesterase inhibitors, experienced slower cognitive decline compared to the typical cognitive decline of Alzheimer's patients as reported in the literature (102). However, the significance of these findings is difficult to assess without a control group for comparison. A randomized controlled trial found that oral supplementation with 1,200 mg/day of lipoic acid for 10 weeks was of no benefit in treating HIV-associated cognitive impairment (103). The results of another randomized trial in 39 patients with Alzheimer's disease suggested that supplementation with fish oil concentrate (high in omega-3 fatty acids) with or without lipoic acid (600 mg/day) for one year could delay the progression in cognitive and functional impairments assessed by the Instrumental Activities of Daily Living (IADL) scoring system compared to placebo (104). Interestingly, patients who took fish oil concentrate together with lipoic acid showed no worsening of global cognitive function (as assessed by the Mini-Mental State Examination [MMSE] score system) over 12 months as opposed to those who took either the fish oil concentrate alone or a placebo (104). Larger trials are needed to confirm these preliminary findings and further evaluate the usefulness of supplemental lipoic acid in the prevention and/or management of neurodegenerative diseases.

Weight management

A 2018 meta-analysis of randomized, placebo-controlled trials found that lipoic acid supplementation in those with high body mass index (BMI) resulted in significant, yet modest, reductions in weight (9 studies) and BMI (11 studies) in the absence of caloric restriction (except in one study) (105). Subgroup analyses revealed that weight loss was greater in overweight versus obese participants, in unhealthy versus healthy participants, with daily doses ≤600 mg, and for intervention period shorter than 10 weeks. There was no reduction in waist circumference with supplemental lipoic acid (5 studies) (105). Substantial weight and BMI reductions with lipoic acid supplementation in overweight or obese subjects were also reported in a prior meta-analysis (106).

Sources

Endogenous biosynthesis

R-lipoic acid is synthesized endogenously by humans (see Metabolism and Bioavailability).

Food sources

R-lipoic acid occurs naturally in food covalently bound to lysine in proteins (lipoyllysine; see **Figure 1**). Although lipoic acid is found in a wide variety of foods from plant and animal sources, quantitative information on the lipoic acid or lipoyllysine content of food is limited; published databases are lacking. Animal tissues with high lipoyllysine content (~1-3 µg/g dry wt) include kidney, heart, and liver, while lipoyllysine-rich vegetables include spinach and broccoli (107). Somewhat lower amounts of lipoyllysine (~0.5 µg/g dry wt) have been measured in tomatoes, peas, and Brussels sprouts.

Supplements

Unlike lipoic acid in foods, lipoic acid in supplements is not bound to protein. Moreover, the amounts of lipoic acid available in dietary supplements (50-600 mg) are likely as much as 1,000 times greater than the amounts that could be obtained from the diet. In Germany, lipoic acid is approved for the treatment of diabetic neuropathies and is available by prescription (108). Lipoic acid is available as a dietary supplement without a prescription in the US. Most lipoic acid supplements contain a racemic mixture of *R*-lipoic acid and *S*-lipoic acid (sometimes noted *d,l*-lipoic acid). Supplements that claim to contain only *R*-lipoic acid are usually more expensive, and information regarding their purity is not publicly available (109). Since taking lipoic acid with a meal decreases its bioavailability, it is generally recommended that lipoic acid be taken 30 min prior to a meal (see also Metabolism and Bioavailability) (8).

***Racemic mixture versus R*-lipoic acid only**

R-lipoic acid is the isomer that is synthesized by plants and animals and functions as a cofactor for mitochondrial enzymes in its protein-bound form (see Biological Activities). Direct comparisons of the bioavailability of the oral racemic mixture and *R*-lipoic acid supplements have not been published. Following the ingestion of *R,S*-lipoic acid, peak plasma concentrations of *R*-lipoic acid were found to be 40%-50% higher than *S*-lipoic acid, suggesting better absorption of *R*-lipoic acid. Both isomers were nonetheless rapidly metabolized and eliminated (6, 8, 11). In rats, *R*-lipoic acid was more effective than *S*-lipoic acid in enhancing insulin-stimulated glucose transport and metabolism in skeletal muscle (110), and *R*-lipoic acid was more effective than *R,S*-lipoic acid and *S*-lipoic acid in preventing cataracts (111). However, all of the published human studies have used *R,S*-lipoic acid (racemic mixture). It has been suggested that the presence of *S*-lipoic acid in the racemic mixture may limit the polymerization of *R*-lipoic acid and enhance its bioavailability (52). At present, it remains unclear which supplemental form is best to use in clinical trials.

Safety

Adverse effects

In general, high-dose lipoic acid administration has been found to have few serious side effects. Intravenous administration of lipoic acid at doses of 600 mg/day for three weeks (112) and oral lipoic acid at doses as high as 1,800 mg/day for six months (113) and 1,200 mg/day for two years (76) did not result in serious adverse effects when used to treat diabetic peripheral neuropathy. There was no significant difference in the incidence of adverse events and serious adverse events in patients with diabetic neuropathy who took 600 mg/day of lipoic acid for four years compared to those in the placebo group (78). Oral intake of 2,400 mg/day for two weeks was also found to be safe in a pilot study that included participants with multiple sclerosis (95). Two mild anaphylactoid reactions and one severe anaphylactic reaction, including laryngospasm, were reported after intravenous lipoic acid administration (55). The most frequently reported side effects of oral lipoic acid supplementation are allergic reactions affecting the skin, including rashes, hives, and itching. Abdominal pain, nausea, vomiting, diarrhea, and vertigo have also been reported, and one trial found that the incidence of nausea, vomiting, and vertigo was dose-dependent (77). Further, malodorous urine has been noted by people taking 1,200 mg/day of lipoic acid orally (95).

Pregnancy and lactation

A retrospective observational study reported that daily oral supplementation with 600 mg of lipoic acid (racemic mixture) during pregnancy and without interruption from a period spanning between week 10 and week 30 of gestation and until the end of week 37 was not associated with any adverse effect in mothers and their newborns (114). In absence of further evidence, lipoic acid supplementation during pregnancy should only be considered under strict medical supervision. The safety of lipoic acid supplements in lactating women has not been established and should thus be discouraged (115).

Children

A case of intoxication was reported in a 20-month old child (10.5 kg bw) after the accidental ingestion of four 600-mg tablets of lipoic acid (116). The child was admitted to hospital with seizure, acidosis, and unconsciousness. Symptomatic management and rapid elimination of lipoic acid led to a full recovery without sequelae within five days. The non-accidental ingestion of a very high dose of lipoic acid led to multi-organ failure and subsequent death of an adolescent girl (117).

Drug interactions

In theory, because lipoic acid supplementation may improve insulin-mediated glucose utilization (see Diabetes mellitus), there is a potential risk of hypoglycemia in diabetic patients using insulin or oral anti-diabetic agents (118). Consequently, blood glucose concentrations should be monitored closely when lipoic acid supplementation is added to diabetes treatment regimens. Yet, one study in 24 healthy volunteers reported no significant drug interactions with the co-administration of a single oral dose of lipoic acid (600 mg) and the oral anti-diabetic agents, glyburide (also called glybenclamide) or acarbose (Precose/Prandase/Glucobay) (119).

Nutrient interactions

Biotin

The chemical structure of biotin is similar to that of lipoic acid, and there is some evidence that high concentrations of lipoic acid can compete with biotin for transport across cell membranes (120, 121). The administration of high doses of lipoic acid by injection to rats decreased the activity of two biotin-dependent enzymes by about 30%-35% (122), but it is not known whether oral or intravenous lipoic acid supplementation substantially increases the requirement for biotin in humans (123).

Phytochemicals

Phytochemicals can be defined, in the strictest sense, as chemicals produced by plants. However, the term is generally used to describe chemicals from plants that may affect health, but are not essential nutrients. While there is ample evidence to support the health benefits of diets rich in fruit, vegetables, legumes, whole grains, and nuts, evidence that these effects are due to specific nutrients or phytochemicals is limited. Because plant-based foods are complex mixtures of bioactive compounds, information on the potential health effects of individual phytochemicals is linked to information on the health effects of foods that contain those phytochemicals.

Select a phytochemical from the list for more information.

The information on dietary phytochemicals from the Linus Pauling Institute's Micronutrient Information Center is now available in a book titled, *An Evidence-based Approach to Phytochemicals and Other Dietary Factors*. The book can be purchased from the Linus Pauling Institute or Thieme Medical Publishers.

α-Carotene, β-Carotene, β-Cryptoxanthin, Lycopene, Lutein, and Zeaxanthin

日本語

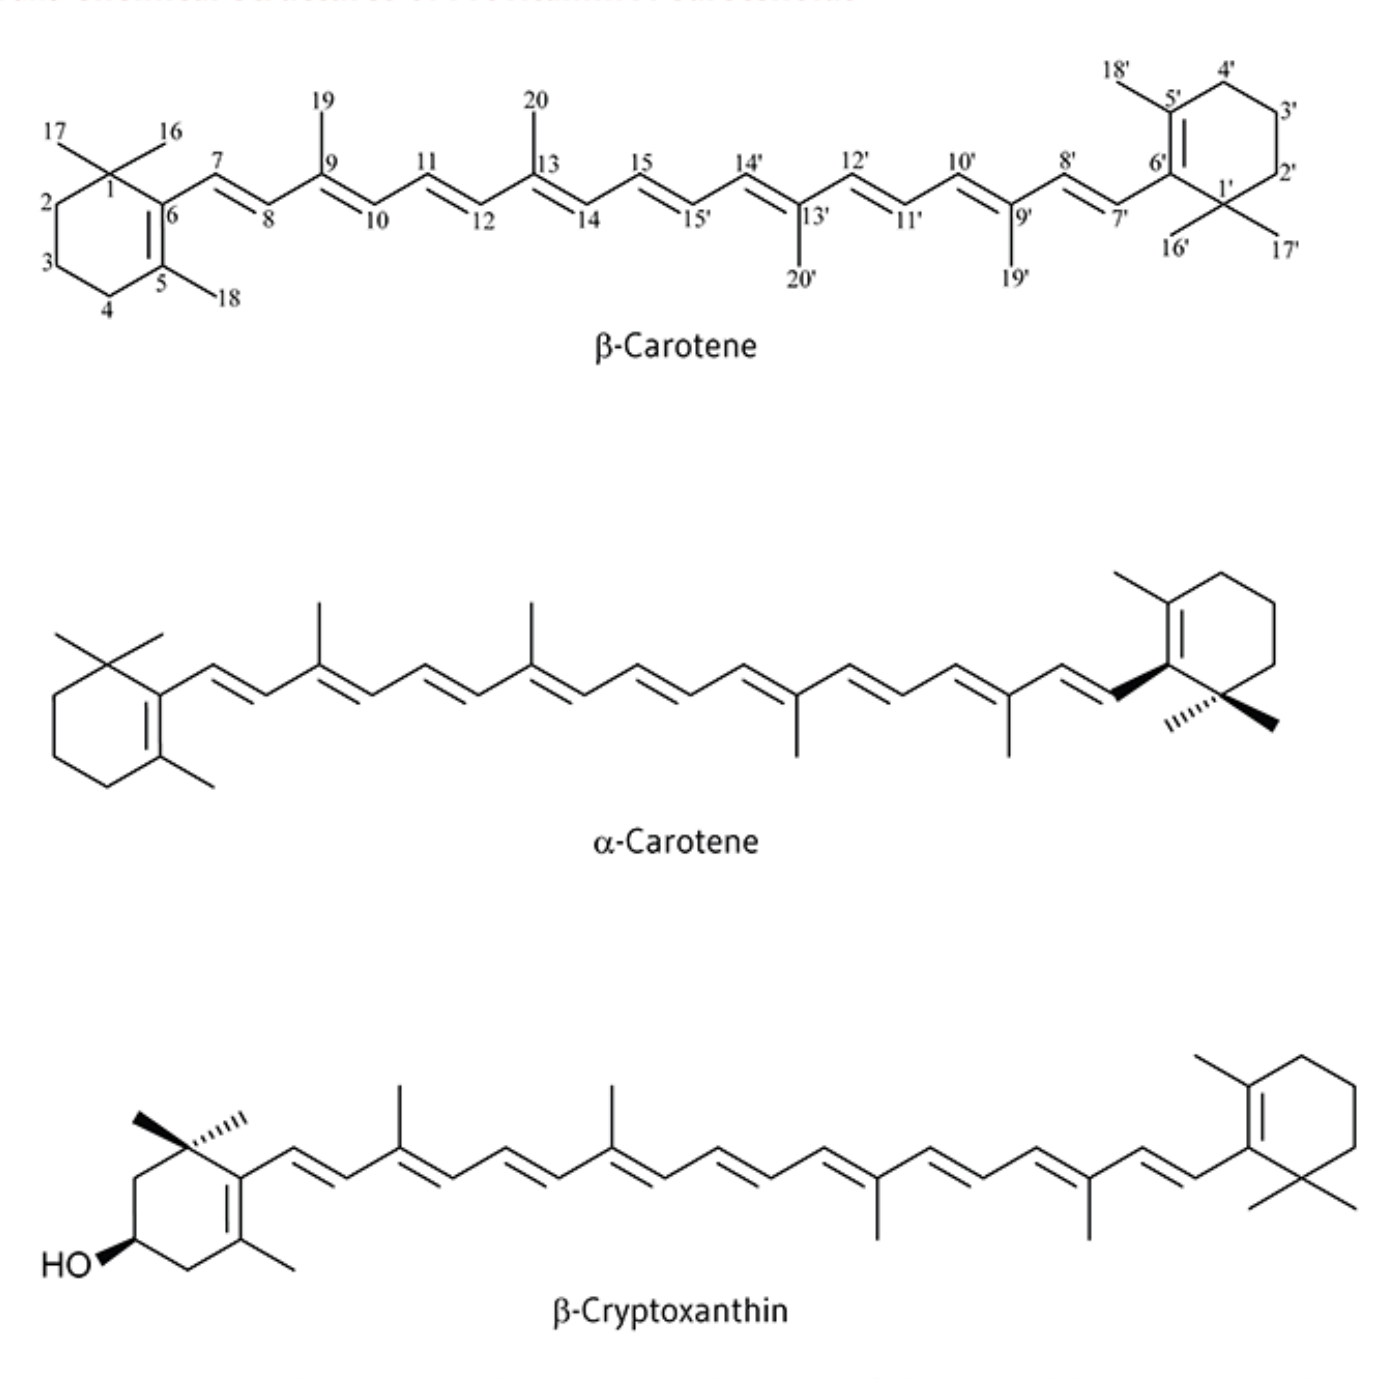
Summary

- Carotenoids are yellow, orange, and red pigments synthesized by plants. The most common carotenoids in North American diets are α-carotene, β-carotene, β-cryptoxanthin, lutein, zeaxanthin, and lycopene. *(More information)*
- Provitamin A carotenoids, α-carotene, β-carotene, and β-cryptoxanthin, can be converted by the body to retinol (vitamin A). In contrast, no vitamin A activity can be derived from lutein, zeaxanthin, and lycopene. *(More information)*
- Dietary lutein and zeaxanthin are selectively taken up into the macula of the eye, where they absorb up to 90% of blue light and help maintain optimal visual function. *(More information)*
- At present, it is unclear whether the biological effects of carotenoids in humans are related to their antioxidant activity and/or other non-antioxidant activities. *(More information)*
- Although the results of observational studies suggest that diets high in carotenoid-rich fruit and vegetables are associated with reduced risks of cardiovascular disease and some cancers, high-dose β-carotene supplements did not reduce the risk of cardiovascular disease or cancer in large randomized controlled trials. *(More information)*
- Two randomized controlled trials found that high-dose β-carotene supplements increased the risk of lung cancer in smokers and former asbestos workers. *(More information)*
- Recent meta-analyses of observational studies reported an inverse association between blood lycopene concentration and risk of developing prostate cancer. To date, most small-scale intervention studies found little-to-no benefit of lycopene supplements in reducing incidence or severity of prostate cancer in high-risk patients. *(More information)*
- Observational studies have suggested that diets rich in lutein and zeaxanthin may help slow the development of age-related macular degeneration (AMD). Randomized controlled trials found that lutein and zeaxanthin supplements could improve visual acuity and slow the progression to advanced AMD in subjects with AMD. *(More information)*
- Evidence is lacking to suggest a role for lutein and zeaxanthin in the management of other eye conditions, including cataracts, diabetic retinopathy, and retinopathy of maturity. *(More information)*
- Carotenoids are best absorbed with fat in a meal. Chopping, puréeing, and cooking carotenoid-containing vegetables in oil generally increase the bioavailability of the carotenoids they contain. *(More information)*

Introduction

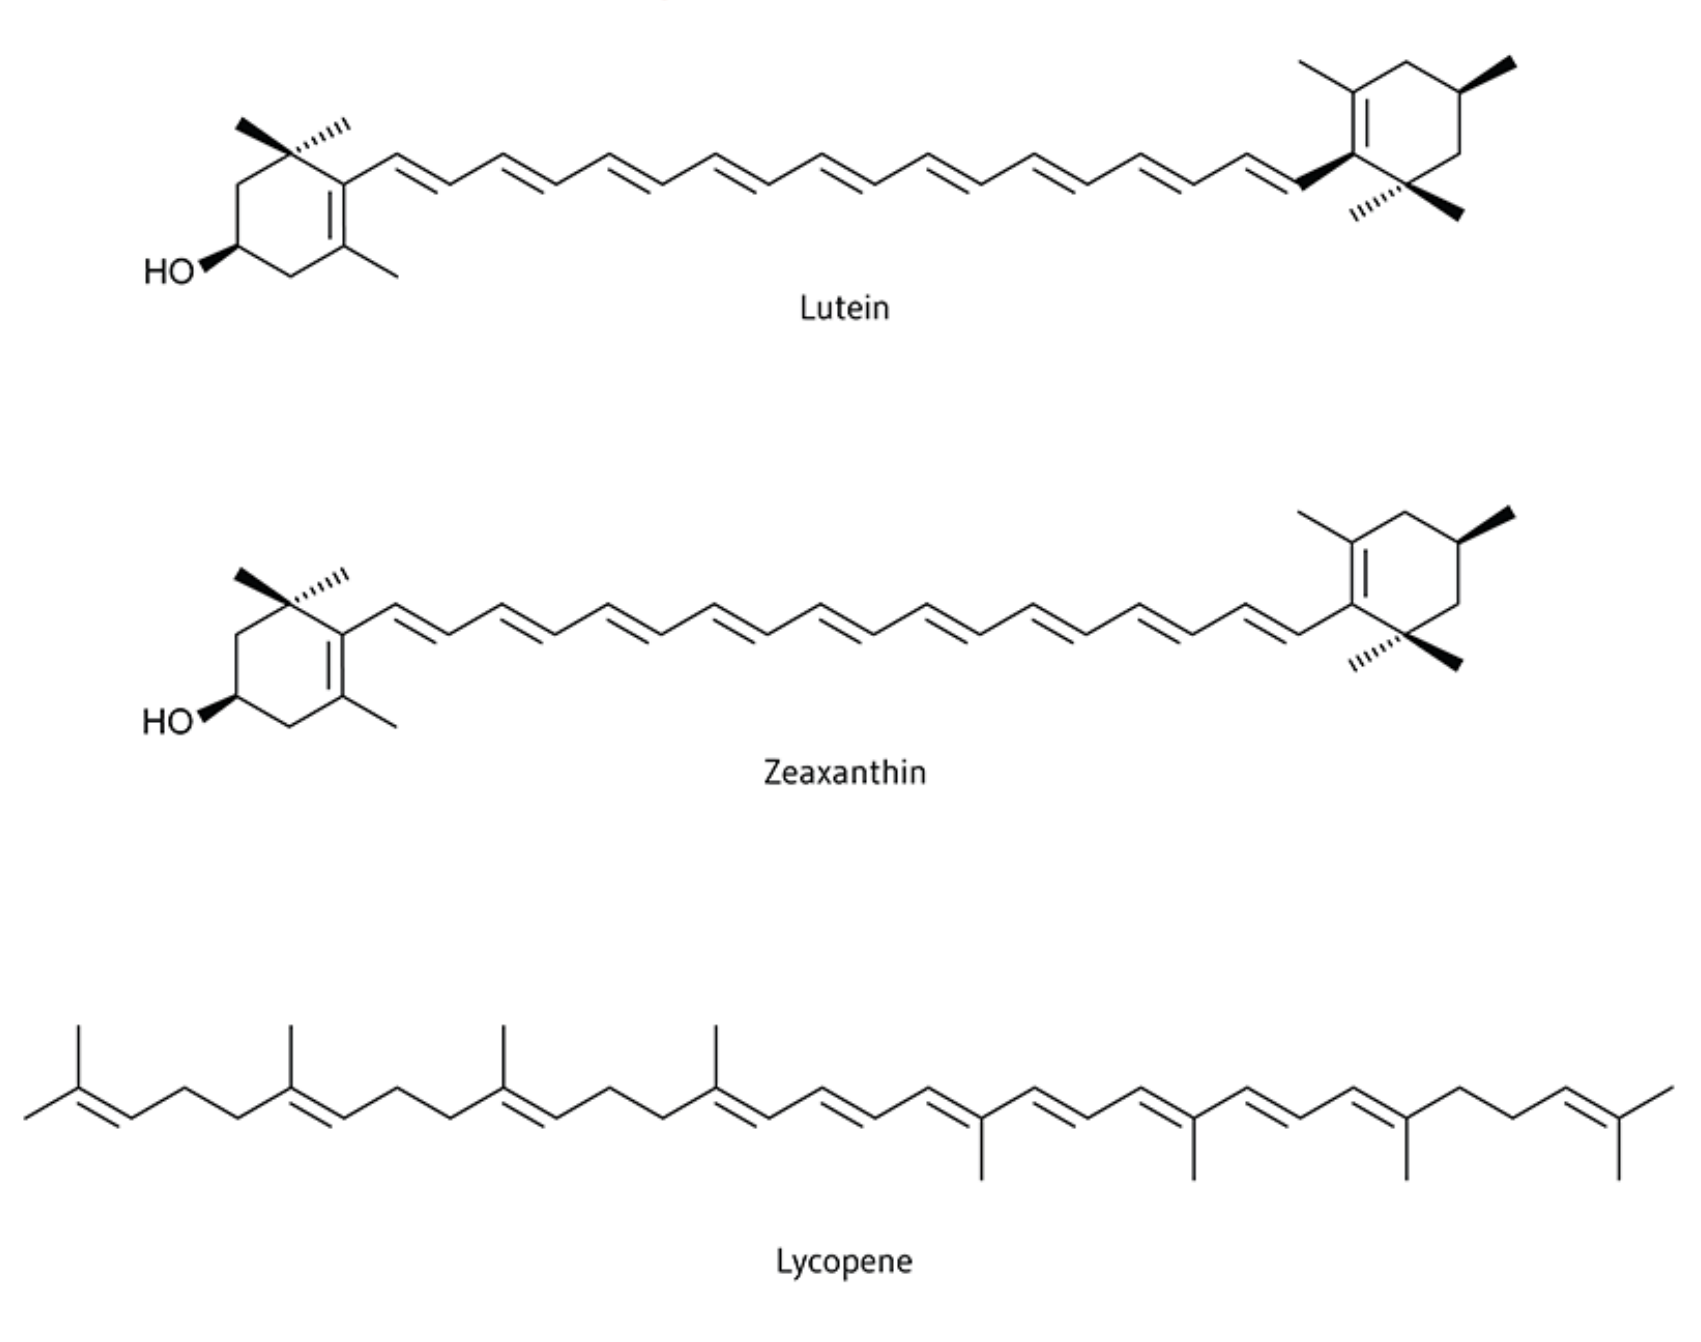
Carotenoids are a class of more than 750 naturally occurring pigments synthesized by plants, algae, and photosynthetic bacteria (1). These richly colored molecules are the sources of the yellow, orange, and red colors of many plants. Fruit and vegetables provide most of the 40 to 50 carotenoids found in the human diet. α-Carotene, β-carotene, β-cryptoxanthin, lutein, zeaxanthin, and lycopene are the most common dietary carotenoids (1). α-Carotene, β-carotene and β-cryptoxanthin are provitamin A carotenoids, meaning they can be converted by the body to retinol (**Figure 1**). Lutein, zeaxanthin, and lycopene are nonprovitamin A carotenoids because they cannot be converted to retinol (**Figure 2**).

Figure 1. *All-trans* Chemical Structures of Provitamin A Carotenoids



β-Carotene, α-carotene, and β-cryptoxanthin are potential sources of vitamin A. All three carotenoids have a long carbon chain terminated at each end by a ionone ring. Carotenoids with oxygen added to ionone rings like β-cryptoxanthin are known as xanthophyll carotenoids. Other xanthophylls commonly found in the human diet are non-provitamin A lutein and zeaxanthin.

Figure 2. *All-trans* Chemical Structures of Nonprovitamin A Carotenoids



Absorption, Metabolism, and Bioavailability

For dietary carotenoids to be absorbed intestinally, they must be released from the food matrix and incorporated into mixed micelles (mixtures of bile salts and several types of lipids). Food processing and cooking help release carotenoids embedded in their food matrix and increase intestinal absorption (1). Moreover, carotenoid absorption requires the presence of fat in a meal. As little as 3 to 5 g of fat in a meal appears sufficient to ensure carotenoid absorption (2, 3), although the minimum amount of dietary fat required may be different for each carotenoid. The type of fat (e.g., medium-chain vs. long-chain triglycerides), the presence of soluble fiber, and the type and amount of carotenoids (e.g., esterified vs. non-esterified) in the food also appear to influence the rate and extent of carotenoid absorption (reviewed in 4). Because they do not need to be released from the plant matrix, carotenoid supplements (in oil) are more efficiently absorbed than carotenoids in food (3). Although carotenoids were initially thought to be absorbed within the cells that line the intestine (enterocytes) only by passive diffusion, recent investigations identified the apical membrane transporters, Scavenger Receptor-class B type I (SR-BI) and Cluster Determinant 36 (CD36), suggesting active uptake of carotenoids as well (5).

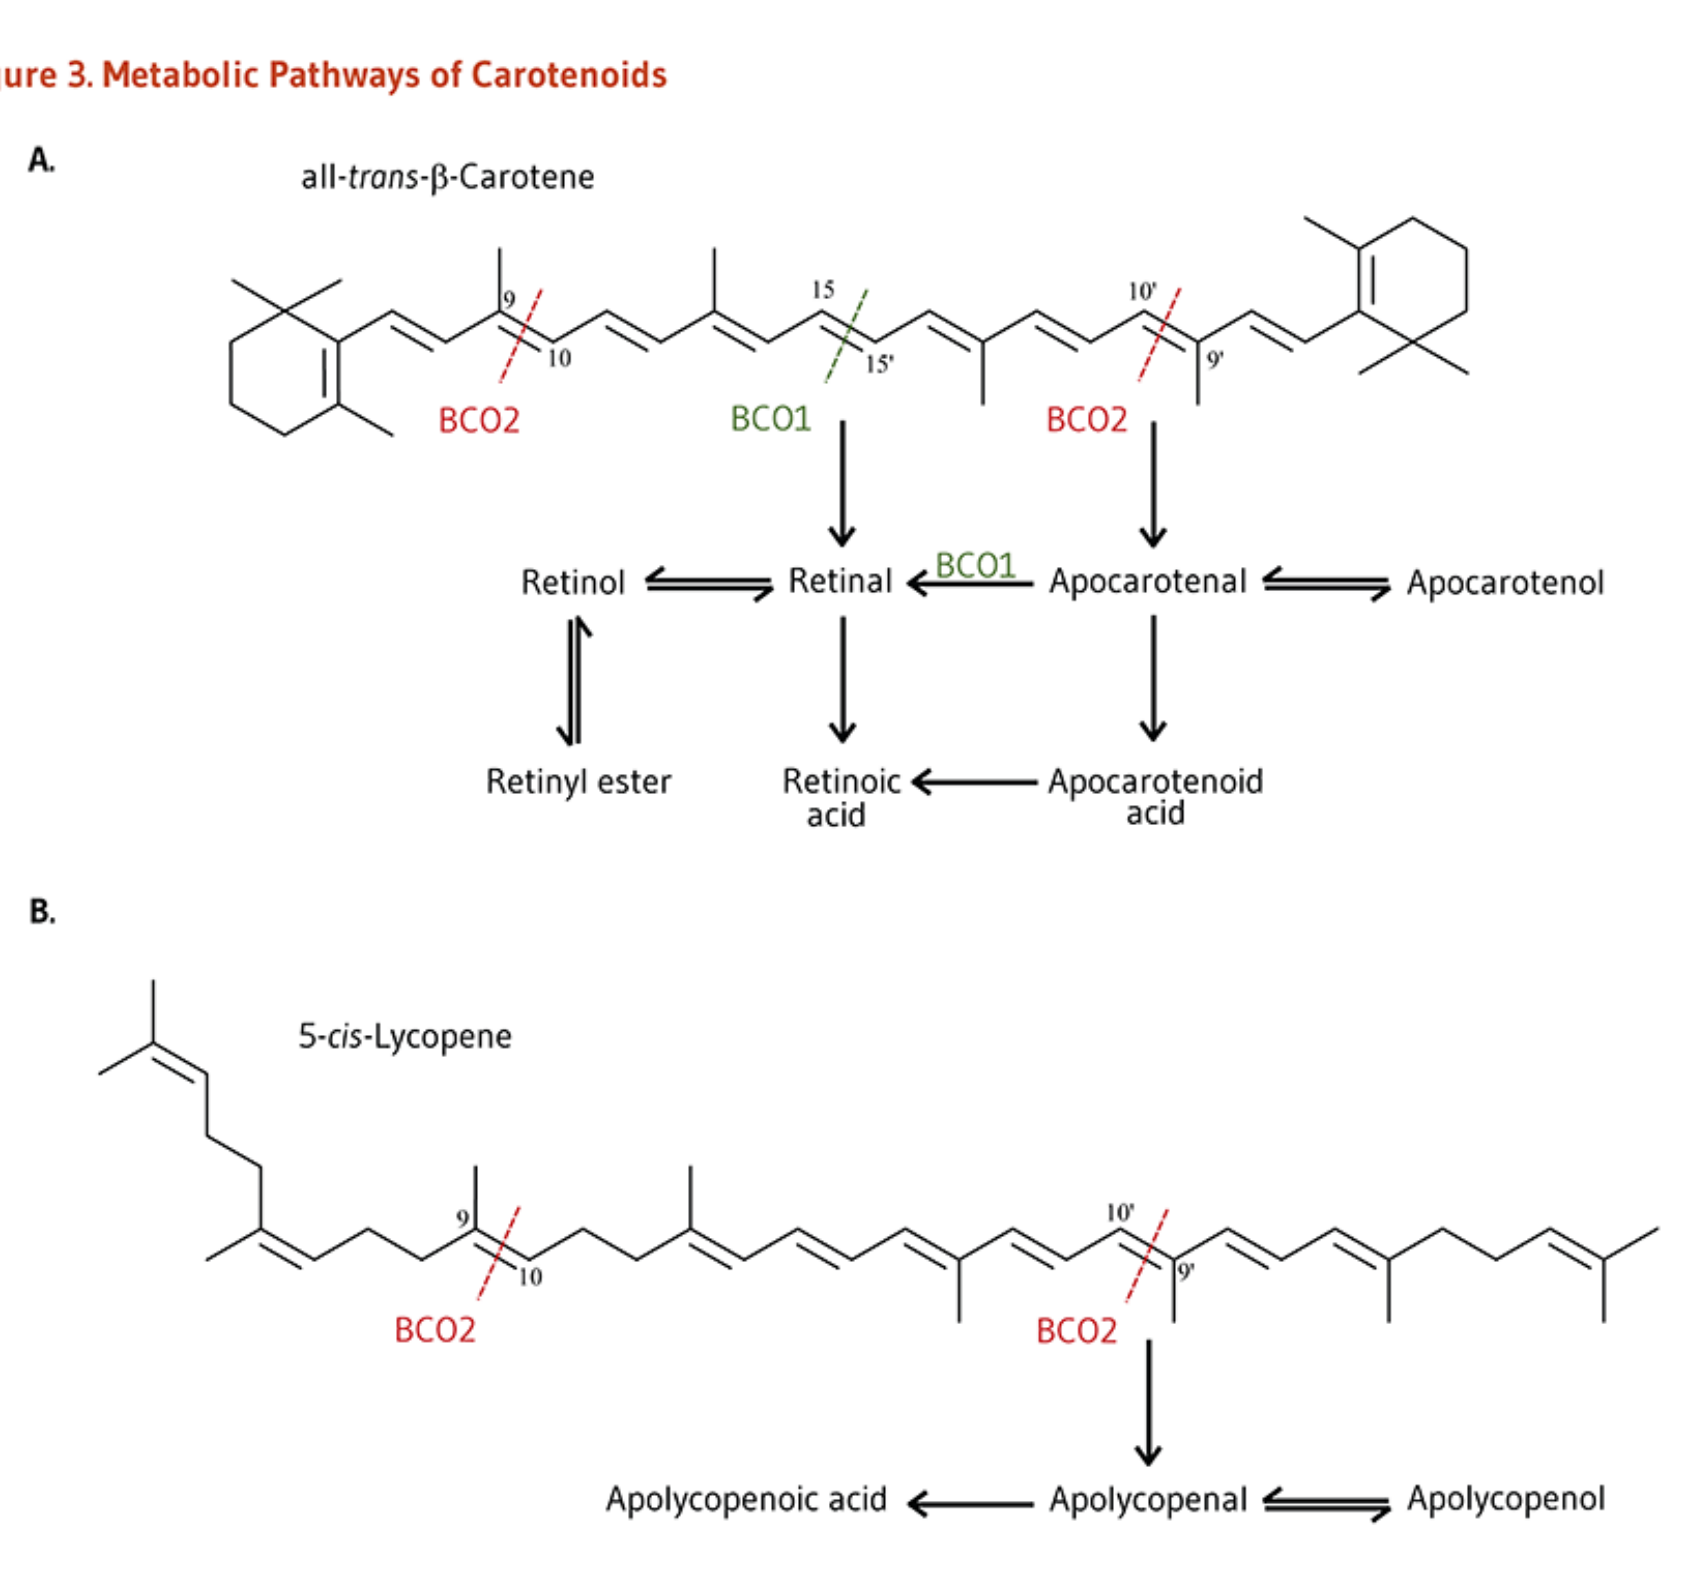
Within the enterocytes, provitamin A carotenoids may be cleaved by either β-carotene 15,15'-oxygenase 1 (BCO1) or by β-carotene 9',10'-oxygenase 2 (BCO2) (**Figure 3**). BCO1 catalyzes the cleavage of provitamin A carotenoids into retinal, which is further reduced to retinol (vitamin A) or oxidized to retinoic acid (the biologically active form of vitamin A). β-Apocarotenal derived from the cleavage of β-carotene by BCO2 can be cleaved further by BCO1 to produce retinal. Although provitamin A carotenoids can be converted into apocarotenals by BCO2, the activity of this enzyme is higher toward nonprovitamin A carotenoids. Conversely, BCO1 shows limited affinity toward nonprovitamin A carotenoids (1).

Within the enterocytes, uncleaved carotenoids and retinyl esters (derived from retinol) are incorporated into triglyceride-rich lipoproteins called chylomicrons, secreted into lymphatic vessels, and then released in the bloodstream (1). Triglycerides are depleted from circulating chylomicrons through the activity of an enzyme called lipoprotein lipase, resulting in the formation of chylomicron remnants. Chylomicron remnants are taken up by the liver, where carotenoids can be cleaved by BCO1/BCO2 or incorporated into lipoproteins and secreted back into the circulation for delivery to extrahepatic tissues. Of note, more hydrophilic molecules in the enterocytes like retinoic acid and apocarotenals can be transported directly to the liver through the portal blood system.

The conversion of provitamin A carotenoids to retinol is influenced by the vitamin A status of the individual (6). The regulatory mechanism involving the intestine-specific homeobox (ISX) transcription factor can block carotenoid uptake and vitamin A production by inhibiting the expression of SR-BI and BCO1. ISX is under the control of retinoid acid and retinoic acid receptor (RAR)-dependent mechanisms such that, when vitamin A stores are high, ISX is activated and both provitamin A carotenoid absorption and conversion to retinol are inhibited. Conversely, during vitamin A insufficiency, the expression of both SR-BI and BCO1 is no longer repressed by ISX, allowing for provitamin A carotenoid absorption and conversion to retinol (1).

Interindividual variations in blood and tissue concentrations of carotenoids have been attributed to genetic differences among individuals. Specifically, a number of single nucleotide polymorphisms (SNPs) — corresponding to changes of one nucleotide in the sequence of genes — have been identified in genes coding for proteins involved in intestinal uptake, transport, and metabolism of carotenoids (7). Specifically, SNPs within genes coding for SR-BI, CD36, and BCO1 are suspected to affect the expression and/or activity of these proteins and, in turn, individual carotenoid status (7).

Figure 3. Metabolic Pathways of Carotenoids



A. BCO1 catalyzes the symmetrical cleavage of provitamin A carotenoids like β-carotene at the 15, 15' double bond to produce one or two molecules of retinal. Retinal can be oxidized to retinoic acid or reduced to retinol, and further converted to retinyl ester for storage or transport. Provitamin A carotenoids may also be cleaved by BCO2 at either the 9,10 or 9',10' double bond, giving rise to apocarotenals. The latter can be converted to apocarotenols or apocarotenoid acids. Apocarotenals and apocarotenoid acids can be converted to retinals and retinoic acids.

B. Nonprovitamin A carotenoids, lutein and zeaxanthin, can be cleaved by BCO2 at either the 9,10 or 9',10' double bond to produce apocarotenals (not shown here). The cleavage of *cis*-lycopene by BCO2 at either the 9,10 or 9',10' double bond produces apolycopenal, which may be oxidized to apolycopenoic acid or reduced to apolycopenol.
BCO1, β-carotene 15,15'-oxygenase 1; BCO2, β-carotene 9',10'-oxygenase 2.

Biological Activities

Provitamin A function

Vitamin A is essential for normal growth and development, immune system function, and vision (see the article on Vitamin A). Currently, the only essential function of carotenoids recognized in humans is that of the provitamin A carotenoids, α-carotene, β-carotene, and β-cryptoxanthin, to serve as a source of vitamin A (8).

Retinol activity equivalents (RAEs)

Provitamin A carotenoids are less easily absorbed than preformed vitamin A and must be converted to retinol and other retinoids by the body (**Figure 3**). The efficiency of conversion of provitamin A carotenoids into retinol is highly variable, depending on factors like food matrix, food preparation, and one's digestive and absorptive capacities (9).

The most recent international standard of measure for vitamin A is retinol activity equivalent (RAE), which represents vitamin A activity as retinol. It has been determined that 2 micrograms (μg) of β-carotene in oil provided as a supplement could be converted by the body to 1 μg of retinol, giving it an RAE ratio of 2:1. However, 12 μg of β-carotene from food are required to provide the body with 1 μg of retinol, giving dietary β-carotene an RAE ratio of 12:1. Other provitamin A carotenoids in food are less easily absorbed than β-carotene, resulting in RAE ratios of 24:1. RAE ratios are shown in **Table 1**.

Table 1. Retinol Activity Equivalent (RAE) Ratios for Preformed Vitamin A and Provitamin A Carotenoids

Quantity Consumed	Quantity Bioconverted to Retinol	RAE Ratio
1 μg of dietary or supplemental preformed vitamin A	1 μg of retinol	1:1
2 μg of supplemental β-carotene	1 μg of retinol	2:1
12 μg of dietary β-carotene	1 μg of retinol	12:1
24 μg of dietary α-carotene	1 μg of retinol	24:1
24 μg of dietary β-cryptoxanthin	1 μg of retinol	24:1

Antioxidant activity

In plants, carotenoids have the important antioxidant function of quenching (deactivating) singlet oxygen, an oxidant formed during photosynthesis (10). Test tube studies indicated that lycopene is one of the most effective quenchers of singlet oxygen among carotenoids (11). They also suggested that carotenoids could inhibit the oxidation of fats (i.e., lipid peroxidation) under certain conditions, but their actions in humans appear to be more complex (12). Although important for plants, the relevance of singlet oxygen quenching to human health is less clear (1).

Nrf2-dependent antioxidant pathway

Some evidence suggests that carotenoids and/or their metabolites may upregulate the expression of antioxidant and detoxifying enzymes via the activation of the nuclear factor E2-related factor 2 (Nrf2)-dependent pathway (reviewed in 13). Briefly, Nrf2 is a transcription factor that is bound to the protein Kelch-like ECH-associated protein 1 (Keap1) in the cytosol. Keap1 responds to oxidative stress signals by freeing Nrf2. Upon release, Nrf2 translocates to the nucleus and binds to the antioxidant response element (ARE) located in the promoter of genes coding for antioxidant/detoxifying enzymes and scavengers. Nrf2/ARE-dependent genes code for numerous mediators of the antioxidant response, including glutamate-cysteine ligase (GCL), glutathione S-transferases (GSTs), thioredoxin, NAD(P)H quinone oxidoreductase 1 (NQO-1), and heme oxygenase 1 (HO-1) (14). A recent study showed an increase in the level of the major antioxidant glutathione and a protection against TNFα-induced oxidative stress in retinal pigment epithelial cells (RPE) following lycopene-mediated Nrf2 activation and GCL induction (15). Nrf2 activation by lycopene also protected RPE against TNFα-mediated proinflammatory signaling involving nuclear factor-κB (NF-κB) activation and intercellular adhesion molecule-1 (ICAM-1) expression (15). Lycopene was shown to trigger Nrf2-mediated antioxidant pathway in various cell types (16-18). At present, evidence from animal and human studies is very limited (13).

Blue light filtering

The long system of alternating double and single bonds common to all carotenoids allows them to absorb light in the visible range of the spectrum (10). This feature has particular relevance to the eye, where lutein, zeaxanthin, and meso-zeaxanthin (derived from lutein) efficiently absorb blue light. Depending on the carotenoid pigment density at the center of the eye's retina (macula), up to 90% of blue light can be absorbed by these pigments. Reducing the amount of short-wavelength light that reaches the critical visual structures of the eye may protect them from light-induced oxidative damage (19). Because the only source of these plant pigments in the eye is diet, a number of observational and intervention studies have examined the potential of dietary and supplemental lutein and zeaxanthin to protect against age-related eye diseases (see Age-related macular degeneration and Cataracts). Supplemental lutein, alone or with zeaxanthin, was found to improve contrast sensitivity and protect against visual fatigue in young and/or healthy individuals (20-23). Lutein has also been suggested to improve visual function through stimulating neuronal signaling efficiency in the eye (24).

Intercellular communication

Carotenoids can facilitate communication between neighboring cells grown in culture by stimulating the synthesis of connexin proteins (25). Connexins form pores (gap junctions) in cell membranes, allowing cells to communicate through the exchange of small molecules. This type of intercellular communication is important for maintaining cells in a differentiated state and is often lost in cancer cells. Carotenoids facilitate intercellular communication by increasing the expression of the gene encoding a connexin protein, an effect that appears unrelated to the vitamin A or antioxidant activities of various carotenoids (26) and involving a retinoic acid receptor (RAR)-independent mechanism (27).

Immune function

Because vitamin A is essential for normal immune system function, it is difficult to determine whether the effects of provitamin A carotenoids are related to their vitamin A activity or other activities of carotenoids. Although some clinical trials have found that β-carotene supplementation improves several biomarkers of immune function (28-30), increasing intakes of lycopene and lutein — carotenoids without vitamin A activity — have not resulted in similar improvements in biomarkers of immune function (31-33).

Deficiency

Although consumption of provitamin A carotenoids (α-carotene, β-carotene, and β-cryptoxanthin) can prevent vitamin A deficiency (see the article on Vitamin A), no overt deficiency symptoms have been identified in people consuming low-carotenoid diets if they consume adequate vitamin A (8). After reviewing the published scientific research in 2000, the Food and Nutrition Board of the Institute of Medicine concluded that the existing evidence was insufficient to establish a recommended dietary allowance (RDA) or adequate intake (AI) for carotenoids. The Board has set an RDA for vitamin A (see the article on Vitamin A). Recommendations by the National Cancer Institute, American Cancer Society, and American Heart Association to consume a variety of fruit and vegetables daily are aimed, in part, at increasing intakes of carotenoids.

Disease Prevention

Cancer

Lung cancer

Dietary carotenoids: Several large prospective cohort studies, including the Nurses' Health Study (NHS) and the Health Professionals Follow-up Study (HPFS), have examined potential associations between carotenoid intake and/or blood concentrations and lung cancer (36). In a meta-analysis of eight prospective cohort studies, including NHS and HPFS, the highest versus lowest quantile of total carotenoid intake was significantly associated with a 21% reduced risk of lung cancer. For the individual carotenoids, the risk of lung cancer was estimated to be 20% and 14% lower with the highest versus lowest intakes of β-cryptoxanthin and lycopene, respectively. In contrast, dietary intakes of β-carotene, α-carotene, and lutein/zeaxanthin were not found to be significantly linked to a reduced risk of developing lung cancer (36). In addition, an analysis of the pooled results of 11 nested case-control and four prospective cohort studies found no association between serum concentrations of total carotenoids, β-carotene, α-lycopene, β-cryptoxanthin, and lutein/zeaxanthin and lung cancer. Only high versus low serum lycopene concentrations could be linked to a 29% lower risk of lung cancer (36). Any protective effect of dietary carotenoids against the development of lung cancer is likely small and not statistically significant (36).

Supplemental β-carotene: The effect of β-carotene supplementation on the risk of developing lung cancer has been examined in three large randomized, placebo-controlled trials. In Finland, the A-Tocopherol Beta-Carotene (ATBC) cancer prevention trial evaluated the effects of 20 mg/day of β-carotene and/or 50 mg/day of α-tocopherol on more than 29,000 male smokers (37), and in the United States, the β-Carotene And Retinol Efficacy Trial (CARET) evaluated the effects of a combination of 30 mg/day of β-carotene and 25,000 IU/day of retinol (preformed vitamin A) in 18,314 men and women who were smokers, former smokers, or had a history of occupational asbestos exposure (38). Unexpectedly, the risk of lung cancer in the groups taking β-carotene supplements was increased by 16% after six years in the ATBC participants and by 28% after four years in the CARET participants. In contrast, the Physicians' Health Study (PHS) examined the effect of β-carotene supplementation (50 mg every other day) on cancer risk in 22,071 male physicians in the United States, of whom only 11% were current smokers (39). In that lower risk population, β-carotene supplementation for more than 12 years was not associated with an increased risk of lung cancer. In addition, in the Linxian General Population trial conducted in about 29,000 Chinese participants, randomization to 15 mg/day of β-carotene, 30 mg/day of α-tocopherol, and 15 μg/day of selenium, was not found to be associated with lung cancer mortality 10 years after the intervention ended (40).

Although the reasons for the increase in lung cancer risk are not yet clear and several mechanisms have been proposed (41). The US Preventive Services Task Force estimated that the risks of high-dose β-carotene supplementation outweigh any potential benefits for cancer prevention and recommended against supplementation, especially in smokers or other high-risk populations (42).

Prostate cancer

Prostate cancer is the most common cancer affecting US men, more prevalent than lung and colorectal cancers (34).

Dietary lycopene: Several early prospective cohort studies have suggested that lycopene-rich diets were associated with significant reductions in the risk of prostate cancer, particularly more aggressive forms (43). However, pooled data analyses of observational studies that examined potential links between dietary intakes and/or circulating concentrations of lycopene and risk of prostate cancer have given mixed results. An early meta-analysis that combined the results of 10 case-control and four prospective studies found that men with the highest intakes of raw tomatoes, cooked tomatoes, or dietary lycopene had a 11 to 19% lower risk of prostate cancer (44). In addition, pooled data from two case-control and five nested case-control studies showed a 26% lower risk of prostate cancer in participants with the highest serum concentrations of lycopene (44). Most recently, a meta-analysis of observational studies found no association of prostate cancer risk with dietary lycopene intakes (10 case-cohort and two prospective cohort studies) but an inverse association with blood lycopene concentrations (two case-control, nine nested case-control, and one cohort studies) (45, 46). Additionally, a meta-analysis of 15 nested case-control studies conducted by the Endogenous Hormones, Nutritional Biomarkers, and Prostate Cancer Collaborative Group showed an inverse association between circulating lycopene concentrations and risk of advanced stage and/or aggressive prostate cancer, while no association was found with risk of non-aggressive or localized disease (47).

While there is considerable scientific interest in the potential for lycopene to help prevent prostate cancer, it is not yet clear whether the prostate cancer risk reduction observed in some observational studies is related to lycopene itself, other compounds in tomatoes, or other factors associated with lycopene-rich diets (48). Of note, the 2014 World Cancer Research Fund International report on *Diet, Nutrition, Physical Activity, and Prostate Cancer* suggested the need for better designed studies to establish whether consumption of lycopene-containing foods could be linked to a lower risk of prostate cancer (49).

Supplemental lycopene: To date, a few short-term, dietary intervention studies using lycopene in patients with precancerous prostate lesions (high grade prostatic intraepithelial neoplasia; HGPIN) or prostate cancer have been completed. Specifically, two small randomized controlled studies have recently examined the effect of lycopene supplementation for up to six months in men with HGPIN (50, 51). The consumption of 30 to 35 mg/day of supplemental lycopene in the form of tomato extract (50), or together with selenium (55 mg/day) and green tea catechins (600 mg/day) (51), showed no benefit on the rate of progression to prostate cancer at six-month (50, 51) and 37-month follow-ups (51). Earlier small trials in men with HGPIN led to similar conclusions (reviewed in 52). Additionally, a randomized controlled trial in men with localized prostate cancer found that supplementation with 15, 30, or 45 mg of lycopene (until prostatectomy) did not significantly increase plasma lycopene concentration, modify the ratio of steroid hormones in blood, or reduce the concentration of markers of proliferation (i.e., prostate-specific antigen [PSA] and Ki-67) compared to placebo (53). In another trial, 54 patients with metastatic prostate cancer were randomized to orchidectomy alone or orchidectomy plus 4 mg/day of lycopene (54). The proportion of complete clinical response to treatment — assessed by serum PSA and/or bone scan returning to normal — and patient survival rate were found to be significantly higher in patients supplemented with lycopene (54).

Large-scale, controlled clinical trials are needed to further examine the safety and efficacy of long-term use of lycopene supplements for prostate cancer prevention or treatment.

Other types of cancer

In a meta-analysis of 12 prospective cohort studies, no association was found between total and individual carotenoid intake and risk of breast cancer, except with β-carotene for which a 5% reduction in breast cancer risk was estimated for every 5 mg/day increment in consumption (55). In a pooled analysis of 14 nested case-control studies and one follow-up study of a clinical trial, reductions in breast cancer risk were found to be associated with blood concentrations of total carotenoids (-26%), α-carotene (-20%), and lutein (-30%) (55). Another study that recalibrated data for consistency across eight large prospective cohorts before pooled analysis found reduced breast cancer risk to be associated with the highest versus lowest quintile of blood concentrations of total carotenoids (-21%), β-carotene (-17%), and lycopene (-22%) (56). Further analyses found an inverse association between the blood concentrations of β-carotene and α-carotene and risk of estrogen receptor-negative (ER-), but not estrogen receptor-positive (ER+), breast tumors (56). A similar result was recently reported in a case-control study nested within the multicenter, large, European Prospective Investigation into Cancer and Nutrition (EPIC) study (57).

Another case-control study nested within the EPIC study found a 31% lower risk of colorectal cancer with the highest versus lowest quartile of β-carotene intake, while no associations were shown with blood concentrations of other carotenoids or total carotenoids (58). The nested case-control study was included in a recent meta-analysis of 22 observational studies that failed to find associations between carotenoid intakes and colorectal cancer (59).

Pooled data from mostly case-control studies also suggested that higher intakes of individual carotenoids, especially β-cryptoxanthin and lycopene, might be associated with a reduced risk of cancers of the mouth, pharynx, and larynx (60). However, the results of case-control studies are more likely to be distorted by bias than results of prospective studies.

Examining blood concentrations of each carotenoid in relation to cancer subsites may help overcome limitations associated with dietary data and differences in carotenoid absorption.

Eye diseases

Age-related macular degeneration

In Western countries, degeneration of the macula, the center of the eye's retina, is a leading cause of blindness in older adults. Long-term blue light exposure and oxidative damage in the outer segments of photoreceptors may lead to drusen and/or pigment abnormalities in the macula, increasing the risk of age-related macular degeneration (AMD) and central blindness.

Dietary lutein and zeaxanthin: The carotenoids found in the retina are lutein and zeaxanthin, which are both of dietary origin, and meso-zeaxanthin, which is derived from lutein. These three carotenoids are present in high concentrations in the macula (known as macular pigment), where they are efficient absorbers of blue light. They may prevent a substantial amount of the blue light entering the eye from reaching the underlying structures involved in vision and protect against light-induced oxidative damage, which is thought to play a role in the pathology of age-related macular degeneration (reviewed in 19). It is also possible, though not proven, that lutein, zeaxanthin, and meso-zeaxanthin, act directly to neutralize oxidants formed in the retina.

Increasing dietary consumption of lutein and zeaxanthin was shown to raise their serum concentration and macular pigment density (61, 62). Some, but not all, observational studies have provided evidence that higher intakes of lutein and zeaxanthin are associated with lower risk of age-related macular degeneration (AMD) (63). While cross-sectional and retrospective case-control studies found that higher levels of lutein and zeaxanthin in the diet (64-66), blood (67, 68), and retina (69, 70) were associated with a lower incidence of AMD, several prospective cohort studies found no relationship between baseline dietary intakes or serum concentrations of lutein and zeaxanthin and the risk of developing AMD over time (71-74). A recent report examined the association between the incidence of AMD and calculated dietary intakes and predicted plasma concentrations of lutein and zeaxanthin in older adults (≥50 years) from two large prospective cohorts, the Nurses' Health Study (NHS; 63,443 women) and the Health Professionals Follow-up Study (HPFS; 38,603 men), followed for 26 years and 24 years, respectively (75). The highest versus lowest quintile of predicted plasma lutein and zeaxanthin scores was associated with a 41% lower risk of advanced AMD, yet no association was found with intermediate AMD. The evidence also suggested that the consumption of about 6 mg/day of lutein and zeaxanthin from fruit and vegetables (compared with less than 2 mg/day) may decrease the risk of advanced AMD (75).

Supplemental lutein and zeaxanthin: The first randomized controlled trial in patients with atrophic AMD found that supplementation with 10 mg/day of lutein slightly improved visual acuity after one year compared to a placebo (76). The effects of long-term lutein supplementation on atrophic AMD were further investigated in combination with antioxidant vitamins and minerals in the Age-Related Eye Disease Study 2 (AREDS2), a multicenter, randomized, double-blind, placebo-controlled trial. In AREDS, oral supplementation with β-carotene (15 mg/day), vitamin C (500 mg/day), vitamin E (400 IU/day), zinc (80 mg/day as zinc oxide), and copper (2 mg/day as cupric oxide) for five years was shown to reduce the risk of developing advanced AMD by 25% (77). In the AREDS2 study conducted in 4,203 participants at risk for developing late AMD, supplemental lutein (10 mg/day) and zeaxanthin (2 mg/day), in combination with β-carotene, vitamin C, vitamin E, zinc, and copper (the 'AREDS' formulation), did not slow the progression to advanced AMD, although subgroup analyses revealed a benefit in those with the lowest dietary intakes of lutein + zeaxanthin (77). A total of 3,036 subjects were further randomized to various combinations of carotenoids; supplementation with lutein and zeaxanthin significantly reduced the risk of progression to late AMD and to neovascular AMD compared to supplementation with β-carotene (78).

Several smaller (n=30-433) randomized controlled trials also suggested that supplementation with xanthophyll carotenoids would be beneficial in the management of AMD (reviewed in 79). A meta-analysis of eight trials that examined the effect of supplemental lutein (6 to 20 mg/day) or/and zeaxanthin (0 to 10 mg/day) in 1,176 AMD subjects for up to 36 months found improvements in visual acuity and contrast sensitivity with increased levels of xanthophyll carotenoids (80). Finally, a recent randomized, placebo-controlled trial found daily consumption of a buttermilk drink with egg yolks enriched with lutein (1.4 mg), zeaxanthin (0.2 mg), and an omega-3 polyunsaturated fatty acid (DHA; 160 mg) for one year improved visual acuity and macular pigment optical density in subjects with drusen and/or retinal pigment abnormalities (about half of them being classified as having early AMD) (81).

Supplemental β-carotene: The first randomized controlled trial designed to examine the effect of a carotenoid supplement on AMD used β-carotene in combination with vitamin C, vitamin E, and zinc because lutein and zeaxanthin were not commercially available as supplements at the time the trial began (82). Although the combination of antioxidants and zinc lowered the risk of developing advanced macular degeneration in individuals with signs of moderate-to-severe macular degeneration in at least one eye, it is unlikely that the benefit was related to β-carotene since it is not present in the retina. Supplementation of male smokers in Finland with 20 mg/day of β-carotene for six years did not decrease the risk of AMD compared to placebo (83). A placebo-controlled trial in a cohort of 22,071 healthy US men found that β-carotene supplementation (50 mg every other day) had no effect on the incidence of age-related maculopathy — an early stage of AMD (84). Recent systematic reviews of randomized controlled trials have concluded that there is no evidence that β-carotene supplementation prevents or delays the onset of AMD (85, 86).

Other retinopathies

Retinopathy of prematurity

Preterm infants have an immature retinal vascular system that places them at risk of developing retinopathy of prematurity (ROP). Basically, preterm birth halts the normal development of retinal vascular system, which results in a retina that is poorly vascularized and highly susceptible to hyperoxia. In order to meet metabolic demand, the hypoxic retina induces the production of proangiogenic factors like VEGF (vascular endothelial growth factor). These factors stimulate the development of new blood vessels (angiogenesis), causing aberrant vessels sprouting from the retina into the vitreous. It is thought that an imbalance between the production of reactive oxygen species (ROS) and the reduced levels of antioxidants in preterm infants contributes to ROP pathogenesis and causes additional damage to the retina (reviewed in 87).

Supplemental lutein and zeaxanthin: A randomized controlled trial in 62 preterm infants (≤32 weeks of gestational age) failed to observe any benefits regarding ROP incidence and severity with lutein (0.5 mg/kg/day) and zeaxanthin (0.02 mg/kg/day) supplemented from the seventh day post birth until about 10 weeks of age (88). In two other multicenter, placebo-controlled trials in a total of 343 preterm infants, a daily oral dose of 0.14 mg of lutein and 0.006 mg of zeaxanthin administered from the first week after birth did not significantly reduce ROP incidence or the rate of progression from early to more advanced stages of ROP occurrence (89, 90). A fourth multicenter, randomized controlled trial in 203 preterm infants found that administration of a formula containing carotenoids (lutein/zeaxanthin, lycopene, and β-carotene) had no effect on ROP incidence but limited the progression to severe ROP stages in infants with mild ROP compared to a carotenoid-free formula (91). Compared with the control formula, preterm infants free of ROP fed the carotenoid-containing formula had significantly increased plasma carotenoid concentrations, which were correlated with greater rod photoreceptor sensitivity (91). More research is needed to examine whether carotenoid supplementation might promote normal photoreceptor development and prevent ROP in preterm infants.

Diabetic retinopathy

Supplementation with lutein and zeaxanthin has been shown to help preserve retina integrity in diabetic rodents by reducing oxidative stress and inflammatory mediators (87). A higher ratio of plasma nonprovitamin A carotenoids (lutein, zeaxanthin, and lycopene) to vitamin A carotenoids (β-carotene, β-carotene, β-cryptoxanthin) was associated with a reduced risk of diabetic retinopathy in a cross-sectional analysis in 111 individuals with type 2 diabetes mellitus (92). Recent data from 1,430 individuals participating in the Atherosclerosis Risk In Communities (ARIC) study found no association between lutein intake and diabetic retinopathy after adjustment for confounding variables (93). To date, the role of carotenoids in the prevention of diabetic retinopathy has not been examined in clinical studies.

Cataracts

The primary function of the eye's lens is to collect and focus light on the retina. Ultraviolet light and oxidants can damage proteins in the lens, causing structural changes that result in the formation of opacities known as cataracts. As people age, cumulative damage to lens proteins often results in cataracts that are large enough to interfere with vision (10). Risk factors other than aging and sunlight exposure include smoking, diabetes mellitus, higher body mass index, and use of estrogen replacement therapy. An estimated 50 million US adults are projected to be affected by age-related cataracts by 2050 (94).

Dietary lutein and zeaxanthin: The observation that lutein and zeaxanthin are the only carotenoids in the human lens has stimulated interest in the potential for increased intakes of lutein and zeaxanthin to prevent or slow the progression of cataracts (reviewed in 79). Large prospective cohort studies have found that men and women with the highest intakes of foods rich in lutein and zeaxanthin, particularly spinach, kale, and broccoli, were 18%-50% less likely to require cataract extraction (95, 96) or develop cataracts (97-99). Moreover, plasma concentrations of lutein and zeaxanthin have been found to be inversely associated to the progression of nuclear cataract. Additional research is required to determine whether these findings are related specifically to lutein and zeaxanthin intake or to other factors associated with diets high in carotenoid-rich foods (63).

Supplemental lutein and zeaxanthin: The Age-related Eye Disease Study 2 (AREDS2) failed to show an effect of supplemental lutein (10 mg/day) and zeaxanthin (2 mg/day; supplementation for a median of 4.7 years) on the risk of developing cataract, on the progression to severe cataract or to cataract surgery, and on visual acuity (100). However, the results might have been confounded by the fact that most participants were better nourished than the general population and/or used multivitamins that have been found to decrease the risk of developing cataract (101). Additional limitations to consider in interpreting the results have been reviewed elsewhere (100). Additional interventions are required to study whether supplemental lutein and zeaxanthin might be helpful in the prevention of cataract.

Supplemental β-carotene: Evidence from observational studies that cataracts were less prevalent in people with high dietary intakes and blood concentrations of carotenoids led to the inclusion of β-carotene supplements in several large randomized controlled trials of antioxidants. The results of those trials have been somewhat conflicting. β-Carotene supplementation (20 mg/day) for more than six years did not affect the prevalence of cataracts or the frequency of cataract surgery in male smokers living in Finland (83). In contrast, a 12-year study of male physicians in the US found that β-carotene supplementation (50 mg every other day) decreased the risk of cataracts in smokers but not in nonsmokers (102). Note that use of β-carotene supplements have been shown to increase the risk of lung cancer in smokers (see Supplemental β-carotene in lung cancer). Three randomized controlled trials examined the effect of an antioxidant combination that included β-carotene, vitamin C, and vitamin E on the progression of cataracts. Two trials found no benefit after supplementation for five years (103) or more than six years (104), but one trial found a small decrease in the progression of cataracts after three years of supplementation (105). Overall, the results of randomized controlled trials suggest that the benefit of β-carotene supplementation in slowing the progression of age-related cataracts does not outweigh the potential risks.

Cardiovascular disease

Dietary carotenoids: Because carotenoids are very soluble in fat and very insoluble in water, they circulate in lipoproteins, along with cholesterol and other fats. Evidence that low-density lipoprotein (LDL) oxidation plays a role in the development of atherosclerosis led scientists to investigate the role of antioxidant compounds like carotenoids in the prevention of cardiovascular disease (106). The thickness of the inner layers of the carotid arteries can be measured noninvasively using ultrasound technology. This measurement of carotid intima-media thickness is considered a reliable marker of atherosclerosis (107). A number of case-control and cross-sectional studies have found higher blood concentrations of carotenoids to be associated with significantly lower measures of carotid artery intima-media thickness (108-113). Additionally, higher plasma carotenoids at baseline have been associated with significant reductions in risk of cardiovascular disease in some prospective cohort studies (114-118) but not in others (119-122).

More recently, an analysis of data from the 2003-2006 US National Health And Nutrition Examination Survey (NHANES) in a sample of 2,856 adults found that serum total carotenoid concentration was inversely associated to blood concentrations of two cardiovascular risk factors, C-reactive protein (CRP) and total homocysteine (123). HDL-cholesterol concentration was found to be positively associated with α-carotene, β-cryptoxanthin, and lutein/zeaxanthin concentrations, but only the latter was inversely associated with LDL-cholesterol (123). Finally, a recent meta-analysis of observational studies reported lower risks of coronary heart disease (-12%) and stroke (-18%) in individuals in the highest versus lowest tertile of blood lutein concentration (124).

While the results of several prospective studies indicate that people with higher intakes of carotenoid-rich fruit and vegetables are at lower risk of cardiovascular disease (122, 125-127), it is not yet clear whether this effect is a result of carotenoids or other factors associated with diets high in carotenoid-rich fruit and vegetables.

Supplemental β-carotene: In contrast to the results of observational studies suggesting that high dietary intakes of carotenoid-rich fruit and vegetables may decrease cardiovascular disease risk, four randomized controlled trials found no evidence that β-carotene supplements in doses ranging from 20 to 50 mg/day were effective in preventing cardiovascular disease (39, 128-130). Based on the results of these randomized controlled trials, the US Preventive Health Services Task Force found good evidence to suggest that β-carotene supplements provided no benefit in the prevention of cardiovascular disease in healthy adults (42). Thus, although diets rich in β-carotene have generally been associated with reduced cardiovascular disease risk in observational studies, there is no evidence that β-carotene supplementation reduces cardiovascular disease risk (131).

Osteoporosis

A recent experimental study found that the administration of β-cryptoxanthin to ovariectomized mice limited bone resorption by inhibiting osteoclast differentiation but had no effect on osteoblast-driven bone formation (132). Yet, evidence of a protective role of β-cryptoxanthin — and other individual carotenoids — against bone loss in humans is scarce. In the prospective Framingham Osteoporosis Study, data analysis of 603 participants found no association between β-cryptoxanthin intake and changes in bone mineral density (BMD) over a four-year period (133). In contrast, intakes of total and individual carotenoids (β-carotene, lycopene, and lutein/zeaxanthin) were positively associated with proximal femur BMD in men over a four-year period, while lycopene intake was positively linked to lumbar spine BMD in women (133). The 17-year follow-up of participants in the Framingham Osteoporosis Study (946 participants) showed those in the highest tertile of total carotenoid intake (median intake: 23.7 mg/day) had a 51% lower risk of hip fracture compared to those in the lowest tertile (median intake: 7.3 mg/day) (134). In a much larger prospective study — the Singapore Chinese Health Study — in 63,257 men and women followed for 10 years, the highest versus lowest quartile of total carotenoid intake was associated with a 37% lower risk of hip fracture in men but not in women (135). Dietary intakes of α- and β-carotene — but not of β-cryptoxanthin, lycopene, and lutein/zeaxanthin — were inversely associated with hip fracture risk in men (135). Nevertheless, in a small, four-year, Japanese prospective cohort study in 457 adults, the risk of osteoporosis was 93% lower in postmenopausal women in the highest versus lowest tertile of serum β-cryptoxanthin concentration (136). No such association was reported with serum concentrations of other individual carotenoids. Whether carotenoid supplementation may help prevent bone loss and reduce the risk of osteoporosis in older individuals is currently unknown.

Cognitive function

Observational studies have suggested that dietary lutein may be of benefit in maintaining cognitive health (137, 138). As stated above, among the carotenoids, lutein and its isomer zeaxanthin are the only two that cross the blood-retina barrier to form macular pigment in the eye. Lutein also preferentially accumulates in the brain (139, 140). Recent studies suggested that lutein and zeaxanthin concentrations in the macula were correlated with brain lutein and zeaxanthin status and might be used as a biomarker to assess cognitive health (140-142). Additionally, in the Georgia Centenarian Study, the analysis of cross-sectional data from 47 centenarian decedents showed a positive association between post-mortem measures of brain lutein concentrations and pre-mortem measures of cognitive function (139). Brain lutein concentrations were found to be significantly lower in individuals with mild cognitive impairment compared to those with normal cognitive function (139). In a small, four-month, double-blind, placebo-controlled study in older women (ages, 60 to 80 years) without cognitive impairment, supplementation with lutein (12 mg/day) and zeaxanthin (~0.5 mg/day) significantly improved cognitive test performance (143). Nevertheless, the Age-related Eye Disease Study 2 (AREDS2) failed to show an effect of supplemental lutein (10 mg/day) and zeaxanthin (2 mg/day; supplementation for a median of 4.7 years) on the cognitive test scores of 3,741 participants (mean age, 72.7 years) (144).

Sources

Food sources

The most prevalent carotenoids in the human diet are α-carotene, β-carotene, β-cryptoxanthin, lycopene, lutein, and zeaxanthin (8). Most carotenoids in foods are found in the *all-trans* form (see **Figure 1** and **Figure 2** above), although cooking may result in the formation of other isomers. The relatively low bioavailability of carotenoids from most foods compared to supplements is partly due to the fact that they are associated with proteins in the plant matrix (145). Chopping, homogenizing, and cooking disrupt the plant matrix, increasing the bioavailability of carotenoids (3). For example, the bioavailability of lycopene from tomatoes is substantially improved by heating tomatoes in oil (146, 147).

α-Carotene and β-carotene

α-Carotene and β-carotene are provitamin A carotenoids, meaning they can be converted in the body to vitamin A. The vitamin A activity of β-carotene in food is $^1/_{12}$ that of retinol (preformed vitamin A). Thus, it would take 12 μg of β-carotene from food to provide the equivalent of 1 μg (0.001 mg) of retinol. The vitamin A activity of α-carotene from foods is $^1/_{24}$ that of retinol, so it would take 24 μg of α-carotene from food to provide the equivalent of 1 μg of retinol. Orange and yellow vegetables like carrots and winter squash are rich sources of α- and β-carotene. Spinach is also a rich source of β-carotene, although the chlorophyll in spinach leaves hides the yellow-orange pigment. Some foods that are good sources of α-carotene and β-carotene are listed in **Table 2** and **Table 3** (148).

Table 2. α-Carotene Content of Selected Foods

Food	Serving	α-Carotene (mg)
Pumpkin, canned	1 cup	11.7
Carrot juice, canned	1 cup (8 fl oz)	10.2
Carrots, cooked	1 cup	5.9
Carrots, raw	1 medium	2.1
Mixed vegetables, frozen, cooked	1 cup	1.8
Winter squash, baked	1 cup	1.4
Plantains, raw	1 medium	0.8
Collards, frozen, cooked	1 cup	0.2
Tomatoes, raw	1 medium	0.1
Tangerines, raw	1 medium	0.09
Peas, edible-podded, frozen, cooked	1 cup	0.09

Table 3. β-Carotene Content of Selected Foods

Food	Serving	β-Carotene (mg)
Carrot juice, canned	1 cup (8 fl oz)	22.0
Pumpkin, canned	1 cup	17.0
Spinach, frozen, cooked	1 cup	13.8
Sweet potato, baked	1 medium	13.1
Carrots, cooked	1 cup	13.0
Collards, frozen, cooked	1 cup	11.6
Kale, frozen, cooked	1 cup	11.5
Turnip greens, frozen, cooked	1 cup	10.6
Pumpkin pie	1 piece	7.4
Winter squash, cooked	1 cup	5.7
Carrots, raw	1 medium	5.1
Dandelion greens, cooked	1 cup	4.1
Cantaloupe, raw	1 cup	3.2

β-Cryptoxanthin

Like α- and β-carotene, β-cryptoxanthin is a provitamin A carotenoid. The vitamin A activity of β-cryptoxanthin from food was estimated to be $^1/_{24}$ that of retinol, so it would take 24 μg of β-cryptoxanthin from food to provide the equivalent of 1 μg of retinol. Orange and red fruit and vegetables like sweet red peppers and oranges are particularly rich sources of β-cryptoxanthin. Some foods that are good sources of β-cryptoxanthin are listed in **Table 4** (148).

Table 4. β-Cryptoxanthin Content of Selected Foods

Food	Serving	β-Cryptoxanthin (mg)
Pumpkin, cooked	1 cup	3.6
Papayas, raw	1 medium	2.3
Sweet red peppers, cooked	1 cup	0.6
Sweet red peppers, raw	1 medium	0.6
Orange juice, fresh	1 cup (8 fl oz)	0.4
Tangerines, raw	1 medium	0.4
Carrots, frozen, cooked	1 cup	0.3

Yellow corn, frozen, cooked	1 cup	0.2
Watermelon, raw	1 wedge (1/16 of a melon that is 15 inches long x 7.5 inches in diameter)	0.2
Paprika, dried	1 teaspoon	0.2
Oranges, raw	1 medium	0.2
Nectarines, raw	1 medium	0.1

Lycopene

Lycopene gives tomatoes, pink grapefruit, watermelon, and guava their red color. It has been estimated that 80% of the lycopene in the US diet comes from tomatoes and tomato products like tomato sauce, tomato paste, and ketchup (catsup) (149). Lycopene is not a provitamin A carotenoid because it cannot be converted to retinol. Some foods that are good sources of lycopene are listed in **Table 5** (148).

Table 5. Lycopene Content of Selected Foods

Food	Serving	Lycopene (mg)
Tomato paste, canned	1 cup	75.4
Tomato purée, canned	1 cup	54.4
Tomato soup, canned, condensed	1 cup	26.4
Vegetable juice cocktail, canned	1 cup	23.3
Tomato juice, canned	1 cup	22.0
Watermelon, raw	1 wedge (1/16 of a melon that is 15 inches long x 7.5 inches in diameter)	13.0
Tomatoes, raw	1 cup	4.6
Ketchup (catsup)	1 tablespoon	2.5
Pink grapefruit, raw	½ grapefruit	1.7
Baked beans, canned	1 cup	1.3

Lutein and zeaxanthin

Although lutein and zeaxanthin are different compounds, they are both classified as xanthophylls and nonprovitamin A carotenoids (see **Figure 2** above). Some methods used to quantify lutein and zeaxanthin in food do not separate the two compounds, so they are typically reported as lutein and zeaxanthin or lutein + zeaxanthin. Both pigments are present in a variety of fruit and vegetables. Dark green leafy vegetables like spinach and kale are particularly rich sources of lutein but poor sources of zeaxanthin (150). Although relatively low in lutein, egg yolks and avocados are highly bioavailable sources of lutein. Good sources of dietary zeaxanthin include yellow corn, orange pepper, orange juice, honeydew (melon), and mango (150). Some foods containing lutein and zeaxanthin are listed in **Table 6** (148).

Table 6. Lutein + Zeaxanthin Content of Selected Foods

Food	Serving	Lutein + Zeaxanthin (mg)
Spinach, frozen, cooked	1 cup	29.8
Kale, frozen, cooked	1 cup	25.6
Turnip greens, frozen, cooked	1 cup	19.5
Collards, frozen, cooked	1 cup	18.5
Dandelion greens, cooked	1 cup	9.6
Mustard greens, cooked	1 cup	8.3
Summer squash, cooked	1 cup	4.0
Peas, frozen, cooked	1 cup	3.8
Winter squash, baked	1 cup	2.9
Pumpkin, cooked	1 cup	2.5
Brussel sprouts, frozen, cooked	1 cup	2.4
Broccoli, frozen, cooked	1 cup	2.0
Sweet yellow corn, boiled	1 cup	1.5
Avocado, raw	1 medium	0.4
Egg yolk, raw	1 large	0.2

For more information on the carotenoid content of certain foods, search USDA's FoodData Central database.

Supplements

Dietary supplements providing purified carotenoids and combinations of carotenoids are commercially available in the US without a prescription. Carotenoids are best absorbed when taken with a meal containing fat.

α-Carotene

Supplements containing a mixture of carotenoids may include α-carotene. As a provitamin A carotenoid, supplemental α-carotene can contribute to fulfill vitamin A requirements. It is not known whether the relative bioavailability of supplemental α-carotene is greater than that of dietary α-carotene.

α-Cryptoxanthin

Supplements containing a mixture of carotenoids may include α-cryptoxanthin. As a provitamin A carotenoid, supplemental α-cryptoxanthin can contribute to fulfill vitamin A requirements. It is not known whether the relative bioavailability of supplemental α-cryptoxanthin is greater than that of dietary α-cryptoxanthin.

β-Carotene

β-Carotene is sold as individual supplements and also found in supplements marketed to promote visual health (151). Commercially available β-carotene supplements usually contain between 1.5 mg and 15 mg of either synthetic β-carotene or natural β-carotene (mainly from the algae *Dunaliella salina*) per softgel capsule (150). As a provitamin A carotenoid, β-carotene may be used to provide all or part of the vitamin A in multivitamin supplements. The provitamin A activity of β-carotene from supplements is much higher than that of β-carotene from food: it takes only 2 micrograms [μg] (0.002 mg) of β-carotene from supplements to provide 1 μg of retinol (preformed vitamin A) compared to 12 μg of dietary β-carotene.

Of note, the β-carotene content of supplements is often listed in international units (IU) rather than μg: 3,000 μg (3 mg) of supplemental β-carotene provides 5,000 IU of vitamin A.

Lycopene

Lycopene has no provitamin A activity. Synthetic lycopene and lycopene from natural sources, mainly tomatoes, are available as nutritional supplements containing up to 15 mg of lycopene per softgel capsule (150).

Lutein and zeaxanthin

Lutein and zeaxanthin are not provitamin A carotenoids. Lutein and zeaxanthin supplements are available as free carotenoids (non-esterified) or as esters (esterified to fatty acids). Both forms appear to have comparable bioavailability (152). Many commercially available lutein and zeaxanthin supplements have much higher amounts of lutein than zeaxanthin (150). Supplements containing only lutein or zeaxanthin are also available.

Safety

Toxicity

β-Carotene

Although β-carotene can be converted to vitamin A, the conversion of β-carotene to vitamin A decreases when body stores of vitamin A are high (see Absorption, Metabolism, and Bioavailability). This may explain why high doses of β-carotene have never been found to cause vitamin A toxicity. High doses of β-carotene (up to 180 mg/day) have been used to treat erythropoietic protoporphyria, a photosensitivity disorder, without toxic side effects (8).

Lycopene, lutein, and zeaxanthin

No toxicities have been reported (153).

Adverse effects

β-Carotene

Increased lung cancer risk: Two randomized controlled trials in smokers and former asbestos workers found that supplementation with 20 to 30 mg/day of β-carotene for 4 to 6 years was associated with significant 16%-28% increases in the risk of lung cancer compared to placebo (see Supplemental β-carotene in lung cancer). Although the reasons for these findings are not yet clear, the potential risk of lung cancer in smokers and other high-risk groups supplemented with high-dose β-carotene outweigh any possible benefits for chronic disease prevention (42). It should be noted that there is no evidence that β-carotene supplementation may harm nonsmokers.

Carotenodermia: High doses of β-carotene supplements (≥30 mg/day) and the consumption of large amounts of carotene-rich food have resulted in a yellow discoloration of the skin (xanthoderma) known as carotenodermia. Carotenodermia is not associated with any underlying health problems and resolves when supplementation with β-carotene is discontinued or dietary carotene intake is reduced.

Lycopene

Lycopenodermia: High intakes of lycopene-rich food or supplements may result in a deep orange discoloration of the skin known as lycopenodermia. Because lycopene is more intensely colored than the carotenes, lycopenodermia may occur at lower doses than carotenodermia (8).

Lutein and zeaxanthin

Adverse effects of lutein and zeaxanthin have not been reported (150).

Safety in pregnancy and lactation

β-Carotene

Unlike vitamin A, high doses of β-carotene taken by pregnant women have not been associated with increased risk of birth defects (8). However, the safety of high-dose β-carotene supplements in pregnancy and lactation has not been well studied. Although there is no reason to limit dietary β-carotene intake, pregnant and breast-feeding women should avoid consuming more than 3 mg/day (1,500 μg RAE/day; 5,000 IU/day) of β-carotene from supplements unless they prescribed under medical supervision.

Other carotenoids

The safety of carotenoid supplements other than β-carotene in pregnancy and lactation has not been established, so pregnant and breast-feeding women should obtain carotenoids from food rather than supplements. There is no reason to limit the consumption of carotenoid-rich fruit and vegetables during pregnancy (150).

Drug interactions

The cholesterol-lowering agents, cholestyramine (Questran) and colestipol (Colestid), can reduce absorption of fat-soluble vitamins and carotenoids, as can mineral oil and Orlistat (Xenical), a drug used to treat obesity (150). Colchicine, a drug used to treat gout, can cause intestinal malabsorption. However, long-term use of 1 to 2 mg/day of colchicine did not affect serum β-carotene concentrations in one study (154). Increasing gastric pH through the use of proton-pump inhibitors (Omeprazole, Lansoprazole) may decrease the absorption of a single dose of a β-carotene supplement, but the effect is unlikely to be clinically significant (155).

Antioxidant supplements and statins (3-hydroxy-3-methylglutaryl-coenzyme A [HMG-CoA] reductase inhibitors)

A three-year randomized controlled trial in 160 patients with documented coronary heart disease (CHD) and low serum high density lipoprotein (HDL) concentrations found that a combination of simvastatin (Zocor) and niacin increased HDL2 levels, inhibited the progression of coronary artery stenosis, and decreased the frequency of cardiovascular events, including myocardial infarction and stroke (156). Surprisingly, when an antioxidant combination of 1,000 mg of vitamin C, 536 mg of *RRR*-α-tocopherol (vitamin E), 100 μg of selenium, and 25 mg of β-carotene daily was taken with the simvastatin-niacin combination, the protective effects were diminished. Since the antioxidants were taken together in this trial, the individual contribution of β-carotene cannot be determined. In contrast, a much larger randomized controlled trial of simvastatin and an antioxidant combination of 297 mg of *RRR*-α-tocopherol, 250 mg of vitamin C, and 20 mg of β-carotene daily in more than 20,000 men and women with CHD or diabetes mellitus found that the antioxidant combination did not diminish the cardioprotective effects of simvastatin therapy over a five-year period (157). These contradictory findings indicate that further research is needed on potential interactions between antioxidant supplements and cholesterol-lowering agents, such as niacin and statins.

Interactions with food

Fat substitute Olestra

In a controlled feeding study, consumption of 18 g/day of the fat substitute Olestra (sucrose polyester; Olean) resulted in a 27% decrease in serum carotenoid concentrations after three weeks (158). Studies in people before and after the introduction of Olestra-containing snacks to the marketplace found that total serum carotenoid concentrations decreased by 15% in those who reported consuming at least 2 g/day of Olestra (159). One study in adults found that those who consumed more than 4.4 g of Olestra weekly experienced a 9.7% decline in total serum carotenoids compared to those not consuming Olestra (160).

Plant sterol- or stanol-containing foods

Some studies found that the regular use of plant sterol-containing spreads resulted in modest, 10%-20% decreases in the plasma concentrations of some carotenoids, particularly α-carotene, β-carotene, and lycopene (see the article on Phytosterols) (161, 162). However, advising people who use plant sterol- or stanol-containing margarines to consume an extra serving of carotenoid-rich fruit or vegetables daily prevented decreases in plasma carotenoid concentrations (163, 164).

Alcohol

The relationships between alcohol consumption and carotenoid metabolism are not well understood. There is some evidence that regular alcohol consumption inhibits the conversion of β-carotene to retinol (165). Increases in lung cancer risk associated with high-dose β-carotene supplementation in two randomized controlled trials were enhanced in those with higher alcohol intakes (38, 166).

Interactions among carotenoids

The results of metabolic studies suggested that high doses of β-carotene competed with lutein and lycopene for absorption when consumed at the same time (167-169). However, the consumption of high-dose β-carotene supplements did not adversely affect serum carotenoid concentrations in long-term clinical trials (170-173).

Summary

- Chlorophyll a and chlorophyll b are natural, fat-soluble chlorophylls found in plants. *(More information)*
- Sodium copper chlorophyllin (SCC) is a semi-synthetic mixture of water-soluble sodium copper salts derived from chlorophyll. *(More information)*
- SCC has been used orally as an internal deodorant and topically in the treatment of slow-healing wounds for more than 50 years without any serious side effects. *(More information)*
- Chlorophylls and SCC form tight molecular complexes with some chemicals known or suspected to cause cancer, and in doing so, may block carcinogenic effects. Carefully controlled studies have not been undertaken to determine whether a similar mechanism might limit uptake of required nutrients. *(More information)*
- Supplementation with SCC before meals substantially decreased a urinary biomarker of aflatoxin-induced DNA damage in a Chinese population at high risk of liver cancer due to unavoidable, dietary aflatoxin exposure from moldy grains and legumes. *(More information)*
- Scientists are hopeful that SCC supplementation will be helpful in decreasing the risk of liver cancer in high-risk populations with unavoidable, dietary aflatoxin exposure. However, it is not yet known whether SCC or natural chlorophylls will be useful in the prevention of cancers in people who are not exposed to significant levels of dietary aflatoxin. *(More information)*

Introduction

Chlorophyll is the pigment that gives plants and algae their green color. Plants use chlorophyll to trap light needed for photosynthesis (1). The basic structure of chlorophyll is a porphyrin ring similar to that of heme in hemoglobin, although the central atom in chlorophyll is magnesium instead of iron. The long hydrocarbon (phytol) tail attached to the porphyrin ring makes chlorophyll fat-soluble and insoluble in water. Chlorophyll a and chlorophyll b represent about 99% of the chlorophyll species found in edible plants (**Figure 1**; 2), while some algae and microalgae contain minor quantities of chlorophyll c pigments (e.g., *Laminaria ochroleuca*, *Undaria pinnatifida*) (3). Chlorophyll a and b only have a small difference in one of the side chains but an intact phytol tail, while the common characteristic of chlorophyll c isoforms is the absence of a phytol tail. These structural differences cause each type of chlorophyll to absorb light at slightly different wavelengths.

Metallo-chlorophyll derivatives, including chlorophyllins, can be chemically synthesized or produced in industrial food processing; these compounds contain zinc, iron, or copper in place of the central magnesium atom (2). The most studied chlorophyllin, sodium copper chlorophyllin (SCC), is a semi-synthetic mixture of sodium copper salts derived from chlorophyll (4, 5). SCC is often simply called 'chlorophyllin' in the older scientific literature, with newer publications specifying whether iron, zinc, copper, or magnesium chlorophyllin were studied. During its synthesis, the magnesium atom at the center of the ring is replaced with copper (or other metals), and the phytol tail is lost. Unlike natural chlorophyll, chlorophyllins (regardless of the metal used) are water-soluble. Although the content of different SCC mixtures may vary, two compounds commonly found in commercial SCC are trisodium copper chlorin e_6 and disodium copper chlorin e_4 (**Figure 2**).

Metabolism and Bioavailability

Little is known about the bioavailability and metabolism of chlorophyll in humans, although it is known that chlorophyll undergoes extensive metabolism once consumed. Animal model studies show only about 1%-3% of chlorophyll is absorbed, while the rest is excreted in the feces, primarily as pheopytin and pyropheophytin metabolites, indicating that significant transformation and microbial metabolism occur in the gastrointestinal tract (reviewed in 2). A recent study in eight healthy adults found pheophytin and pheophorbide derivatives in the blood of most subjects following consumption of 1.2 kg boiled spinach, a concentrated source of chlorophyll (6).

Sodium copper chlorophyllin was originally thought to be poorly absorbed because of its lack of apparent toxicity. However, a placebo-controlled clinical trial found that significant amounts of copper chlorin e$_4$ in the serum of people taking chlorophyllin tablets (300 mg/day) (7), indicating that it is indeed absorbed. *In vitro* studies have found chlorin e$_4$ to have a higher stability than chlorin e$_6$(2).

More research, however, is needed to understand the bioavailability and metabolism of natural chlorophylls and chlorin compounds in synthetic chlorophyllin.

Biological Activities

Complex formation with other molecules

Chlorophyll and sodium copper chlorophyllin are able to form tight molecular complexes with certain chemicals known or suspected to cause cancer, including polyaromatic hydrocarbons found in tobacco smoke (8), some heterocyclic amines found in cooked meat (9), and aflatoxin-B$_1$ (10). The binding of chlorophyll or SCC to these potential carcinogens may interfere with gastrointestinal absorption of potential carcinogens, reducing the amount that reaches susceptible tissues (11). This has been demonstrated in humans: a cross-over study in three volunteers that used accelerator mass spectrometry to study the pharmacokinetics of an ultra-low dose of aflatoxin-B$_1$ found a 150-mg dose of either SCC or chlorophyll could decrease absorption of aflatoxin-B$_1$ (12).

Antioxidant effects

SCC can neutralize several physically relevant oxidants *in vitro* (13-16), and limited data from animal studies suggest that SCC supplementation may decrease oxidative damage induced by chemical carcinogens and radiation (17, 18). While chlorophyll and its derivatives have demonstrated antioxidant activity in *in vitro* assays (15, 19), the relevance of these findings to humans is not clear.

Modification of the metabolism and detoxification of carcinogens

To initiate the development of cancer, some chemicals (procarcinogens) must first be metabolized to active carcinogens that are capable of damaging DNA or other critical molecules in susceptible tissues. Since enzymes in the cytochrome P450 family are required for the activation of some procarcinogens, inhibition of cytochrome P450 enzymes may decrease the risk of some types of chemically induced cancers. *In vitro* studies indicate that SCC may decrease the activity of cytochrome P450 enzymes (8, 20, 21). Phase II biotransformation enzymes promote the elimination of potentially harmful toxins and carcinogens from the body. Limited data from animal studies indicate that SCC may increase the activity of the phase II enzyme quinone reductase (22).

Therapeutic effects

One *in vitro* study showed that human colon cancer cells undergo cell cycle arrest after treatment with SCC (23). The mechanism involved inhibition of ribonucleotide reductase activity. Ribonucleotide reductase plays a pivotal role in DNA synthesis and repair and is a target of currently used cancer therapeutic agents, such as hydroxyurea (23). While this may provide a potential avenue for SCC in the clinical setting, sensitizing cancer cells to DNA damaging agents, *in vivo* studies are needed.

Metal absorption

The porphyrin structure of chlorophyll is analogous to the heme structure found in blood and muscle tissue. Because heme-bound iron has higher bioavailability than nonheme iron (the most common form of iron in plant-based sources, e.g., legumes, spinach), iron uptake from iron chlorophyll is of interest. Toxicity studies in rats suggest iron chlorophyllin is generally safe for mammalian consumption (24). *In vitro* studies demonstrate that iron chlorophyllin is as good as heme in delivering iron to intestinal cells, and significantly better than the most common supplemental form of iron (i.e., ferrous sulfate) when incorporated into most food matrices (25). However, work in this area is nascent and has not yet been validated in humans. It is also not known if metallo-chlorophyll derivatives of copper or zinc increase absorption of these essential divalent metals.

Disease Prevention

Aflatoxin-associated liver cancer

Aflatoxin-B$_1$ (AFB$_1$), a liver carcinogen produced by certain species of fungus, is found in moldy grains and legumes, including corn, peanuts, and soybeans (4, 11). In hot, humid regions of Africa and Asia with improper grain storage facilities, high levels of dietary AFB$_1$ are associated with increased risk of hepatocellular carcinoma. Moreover, the combination of hepatitis B infection and high dietary AFB$_1$ exposure increases the risk of hepatocellular carcinoma still further. In the liver, AFB$_1$ is metabolized to a carcinogen capable of binding DNA and causing mutations. In animal models of AFB$_1$-induced liver cancer, administration of SCC at the same time as dietary AFB$_1$ exposure significantly reduces AFB$_1$-induced DNA damage in the livers of rainbow trout and rats (26-28) and dose-dependently inhibits the development of liver cancer in trout (29). Likewise, natural chlorophyll has also been found to inhibit AFB$_1$-induced liver cancer in the rat (28). Collectively, this evidence supports a role for SCC and/or chlorophyll itself in limiting cancer initiation. In contrast, data suggest a limited role for SCC in influencing cancer progression. For example, one rat study found that SCC did not protect against aflatoxin-induced liver damage when given after tumor initiation (30).

Because of the long time period between AFB$_1$ exposure and the development of cancer in humans, an intervention trial might require as long as 20 years to determine whether SCC supplementation can reduce the incidence of hepatocellular carcinoma in people exposed to high levels of dietary AFB$_1$. However, a biomarker of AFB$_1$-induced DNA damage (AFB$_1$-N^7-guanine) can be measured in the urine, and high urinary levels of AFB$_1$-N^7-guanine have been associated with significantly increased risk of developing hepatocellular carcinoma (31). In order to determine whether chlorophyllin could decrease AFB$_1$-induced DNA damage in humans, a randomized, placebo-controlled intervention trial was conducted in 180 adults residing in a region in China where the risk of hepatocellular carcinoma is very high due to unavoidable, dietary AFB$_1$ exposure and a high prevalence of chronic hepatitis B infection (32). Participants took either 100 mg of SCC or a placebo before meals three times daily. After 16 weeks of treatment, urinary levels of AFB$_1$-N^7-guanine were 55% lower in those taking SCC than in those taking the placebo, suggesting that SCC supplementation before meals can substantially decrease AFB$_1$-induced DNA damage. Although a reduction in hepatocellular carcinoma has not yet been demonstrated in humans taking SCC, scientists are hopeful that supplementation will provide some protection to high-risk populations with unavoidable, dietary AFB$_1$ exposure (11).

It is not known whether SCC will be useful in the prevention of cancers in people who are not exposed to significant levels of dietary AFB$_1$, as is the case for most people living in the US. Many questions remain to be answered regarding the exact mechanisms of cancer prevention by SCC, the implications for the prevention of other types of cancer, and the potential for natural chlorophylls in the diet to provide cancer protection.

Therapeutic Uses of Chlorophyllin

Internal deodorant

Observations in the 1940s and 1950s that topical SCC had deodorizing effects on foul-smelling wounds led clinicians to administer SCC orally to patients with colostomies and ileostomies in order to control fecal odor (33). While early case reports indicated that SCC doses of 100 to 200 mg/day were effective in reducing fecal odor in ostomy patients (34, 35), a placebo-controlled trial found that 75 mg of oral SCC three times daily was no more effective than placebo in decreasing fecal odor assessed by colostomy patients 36. Several case reports have been published indicating that oral SCC (100-300 mg/day) decreased subjective assessments of urinary and fecal odor in incontinent patients (33, 37).

Trimethylaminuria is a hereditary disorder characterized by the excretion of trimethylamine, a compound with a “fishy” or foul odor. One study in a small number of Japanese patients with trimethylaminuria found that oral SCC (60 mg three times daily) for three weeks significantly decreased urinary trimethylamine concentrations (38).

Wound healing

Research in the 1940s indicated that chlorophyllin slowed the growth of certain anaerobic bacteria in the test tube and accelerated the healing of experimental wounds in animals. These findings led to the use of topical SCC solutions and ointments in the treatment of persistent open wounds in humans (39). During the late 1940s and 1950s, a series of largely uncontrolled studies in patients with slow-healing wounds, such as vascular ulcers and pressure (decubitus) ulcers, reported that the application of topical SCC promoted healing more effectively than other commonly used treatments (40, 41). In the late 1950s, SCC was added to papain and urea-containing ointments used for the chemical debridement of wounds in order to reduce local inflammation, promote healing, and control odor (33). SCC-containing papain/urea ointments are still available in the US by prescription (42). Several studies have reported that such ointments are effective in wound healing (43). A spray formulation of the papain/urea/SCC therapy is also available (44).

Skin conditions

A few small studies have investigated SCC as a topical treatment for various skin conditions. In a pilot study of 10 adults (ages 18-30 years) who had mild-to-moderate acne vulgaris and enlarged facial pores, twice daily application of a 0.1% liposomal SCC gel for three weeks improved a number of clinical parameters of the Global Acne Assessment Scale (i.e., facial oiliness, facial blotchiness, presence and size of facial pores, and number of acne lesions) compared to baseline (45). Additionally, a pilot study in 10 women (ages 40 years or older) with noticeable photodamage and solar lentigines found that twice daily topical application of a gel containing 0.66% SCC complex salts for eight weeks improved various clinical measures, including tactile and visual roughness of facial skin, skin radiance, fine lines, pore size, and overall photodamage (46). A few case reports have also observed some improvement in facial redness and rosacea with application of topical SCC (47).

While the reports from these studies are interesting, placebo-controlled clinical trials are needed to determine whether SCC may have utility in treating various skin conditions.

Sources

Chlorophylls

Chlorophylls are the most abundant pigments in plants, with chlorophyll a being two to four times as prevalent as chlorophyll b (6, 48). Dark-green leafy vegetables like spinach are rich sources of natural chlorophylls. The chlorophyll content of selected vegetables are presented in **Table 1** (49).

Table 1. Chlorophyll Content of Selected Raw Vegetables

Food	Serving	Chlorophyll (mg)
Spinach	1 cup	23.7
Parsley	½ cup	19.0
Cress, garden	1 cup	15.6
Green beans	1 cup	8.3
Arugula	1 cup	8.2
Leeks	1 cup	7.7
Endive	1 cup	5.2
Sugar peas	1 cup	4.8
Chinese cabbage	1 cup	4.1

Food and supplements

Chlorophyll

Green algae like chlorella are often marketed as supplemental sources of chlorophyll. Because natural chlorophyll is not as stable as SCC and is much more expensive, most over-the-counter chlorophyll supplements actually contain sodium copper chlorophyllin.

Sodium copper chlorophyllin

Oral preparations of sodium copper chlorophyllin (also called chlorophyllin copper complex) are available as a dietary supplement and as an over-the-counter drug (Derifil) used to reduce odor from colostomies and ileostomies, or to reduce fecal odor due to incontinence (50). Oral doses of 100 to 300 mg/day in three divided doses have been used to control fecal and urinary odor (see Therapeutic Uses of Chlorophyllin).

In the US, SCC is found in minor quantities in some types of green table olives (51). It is also used as a green color additive in foods like chewing gum (52), as well as in drugs and cosmetics (53).

Zinc chlorophyll derivatives

In US supermarkets, canned green beans thermally processed in a zinc chloride solution to produce zinc chlorophyll derivatives within the green beans themselves are sold under the trademarked name "veri-green" (54). Because zinc chlorophyll derivatives are more robust to heat and acid treatment, they better retain a bright green color as compared to native magnesium-bound chlorophyll (48).

Safety

Natural chlorophylls are not known to be toxic, and no toxic effects have been attributed to chlorophyllin despite more than 50 years of clinical use in humans (11, 33, 39). When taken orally, supplemental chlorophyll or sodium copper chlorophyllin may cause green discoloration of urine or feces, or yellow or black discoloration of the tongue (55). There have also been occasional reports of diarrhea related to oral SCC use. When applied topically to wounds, SCC has been reported to cause mild burning or itching in some cases (56). Oral chlorophyllin may result in false positive results on guaiac card tests for occult blood (57). Since the safety of chlorophyll or chlorophyllin supplements has not been tested in pregnant or lactating women, they should be avoided during pregnancy and lactation.

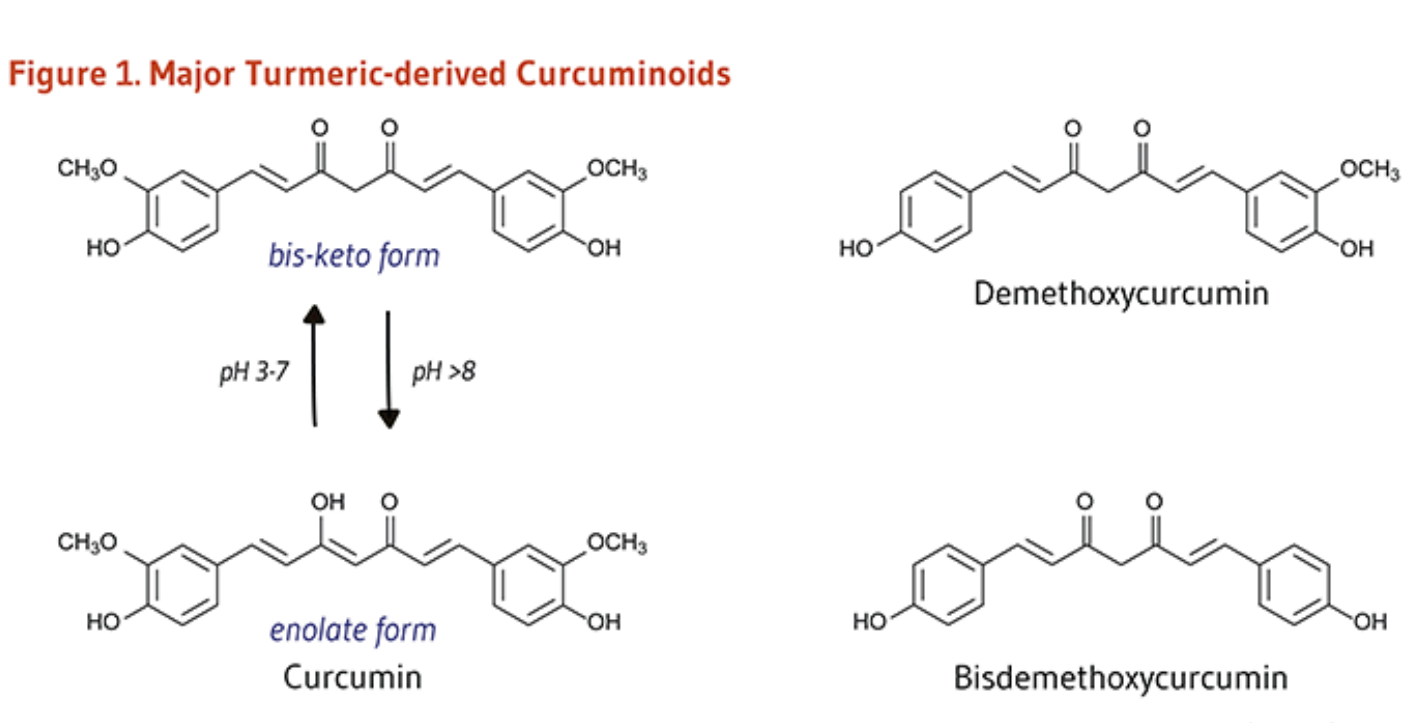
Summary

- Curcumin is a biologically active polyphenolic compound found in turmeric, a spice derived from the rhizomes of the plant *Curcuma longa* Linn. Commonly consumed in Asian countries, turmeric has been used for medicinal purposes for centuries. *(More information)*
- Mounting evidence from preclinical studies shows that curcumin modulates numerous molecular targets and exerts antioxidant, anti-inflammatory, anticancer, and neuroprotective activities. *(More information)*
- In humans, curcumin taken orally is poorly absorbed and rapidly metabolized and eliminated. Therefore, the potential of curcumin as a therapeutic agent is limited by its poor bioavailability. *(More information)*
- Current evidence suggesting that curcumin may help prevent and/or treat colorectal cancer and type 2 diabetes mellitus is very limited. Yet, several clinical trials designed to assess the safety and efficacy of curcumin alone or with first-line treatment in patients with breast, prostate, pancreatic, lung, or colorectal cancer are under way. *(More information)*
- While a few preliminary trials suggested that curcumin may have anti-inflammatory activities in humans, larger randomized controlled trials are still needed to establish the efficacy of curcumin as an anti-inflammatory agent against rheumatoid arthritis, ulcerative colitis, and radiotherapy-induced dermatitis. *(More information)*
- There is currently no substantial evidence showing that curcumin may improve cognitive performance in older adults with or without cognitive impairments. Yet, some preclinical studies have found curcumin prevented or reversed certain pathological features of Alzheimer’s disease (AD). A number of clinical trials designed to assess whether curcumin might help prevent or treat AD are under way. *(More information)*
- Long-term clinical trials are required to confirm whether curcumin could exhibit long-lasting antidepressant effects in patients suffering from major depressive disorder. *(More information)*
- Oral supplementation with curcumin is generally regarded as safe, especially because of its low bioavailability. However, use of curcumin supplements may affect the efficacy or increase the toxicity of a wide range of drugs when taken concurrently. *(More information)*

Introduction

Turmeric is a spice derived from the rhizomes of the tropical plant *Curcuma longa* Linn, which is a member of the ginger family (*Zingiberaceae*). Rhizomes are horizontal underground stems that send out shoots, as well as roots. The bright yellow-orange color of turmeric comes mainly from fat-soluble, polyphenolic pigments known as curcuminoids. Curcumin, the principal curcuminoid found in turmeric, is generally considered its most active constituent (1). Other curcuminoids found in turmeric include demethoxycurcumin and bisdemethoxycurcumin (**Figure 1**). In addition to its use as a spice and pigment, turmeric has been used in India for medicinal purposes for centuries (2). More recently, evidence that curcumin may have anti-inflammatory and anticancer activities has renewed scientific interest in its potential to prevent and treat disease.

Figure 1. Major Turmeric-derived Curcuminoids



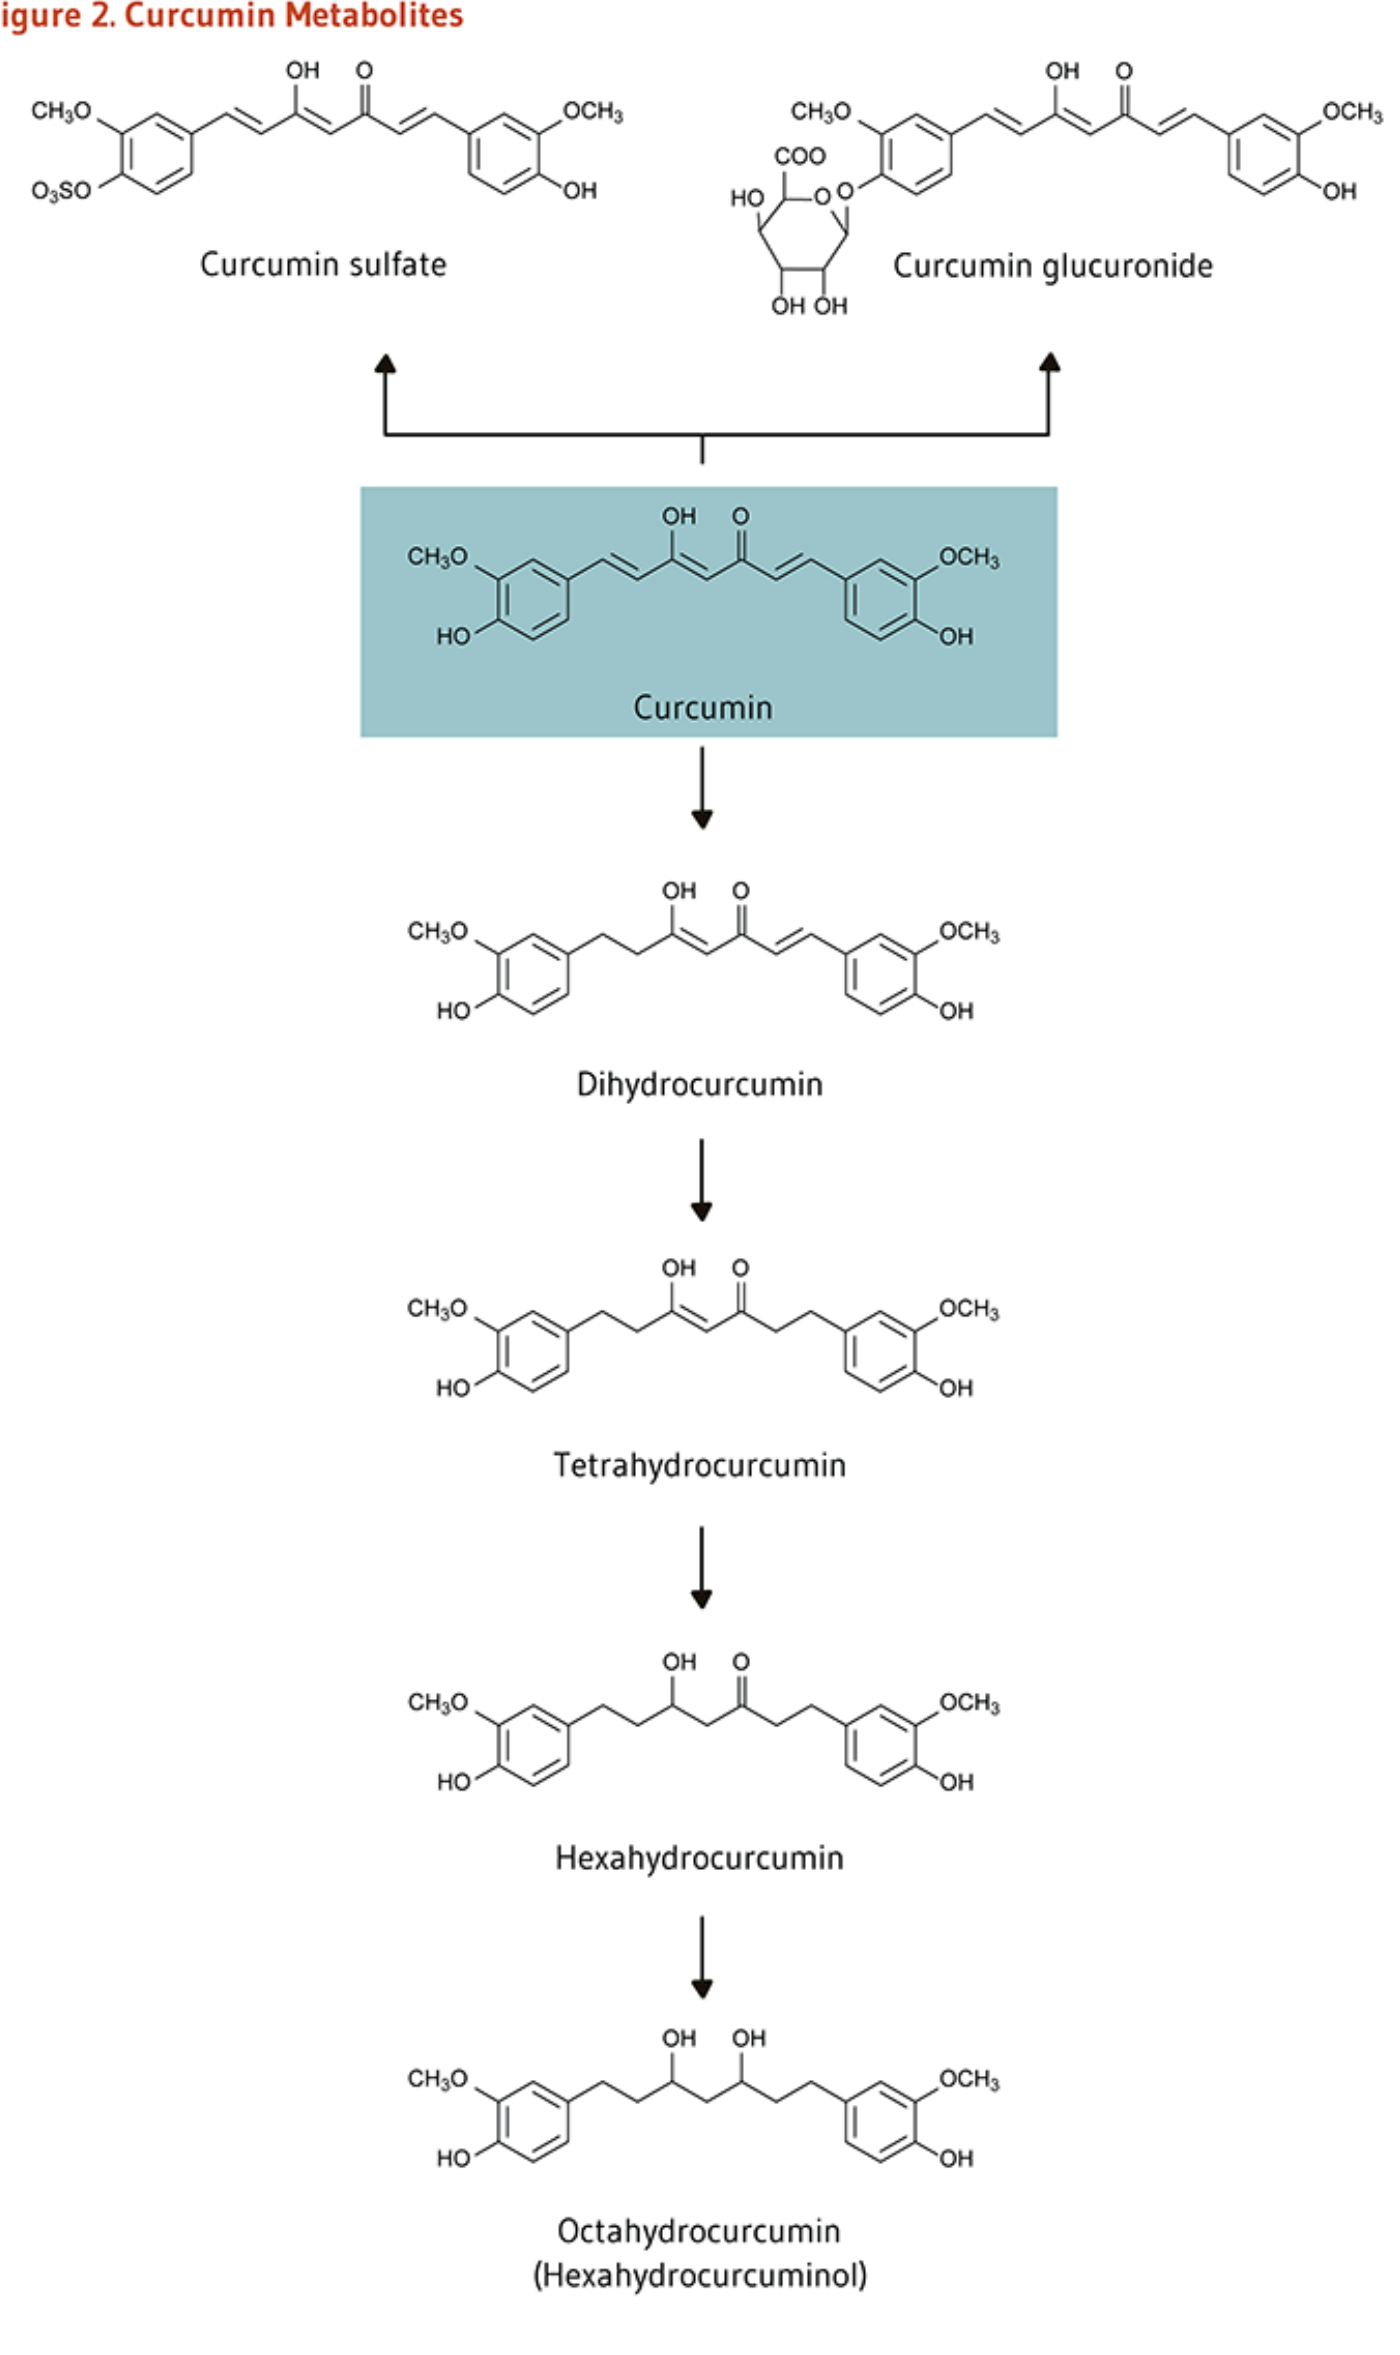
Curcuminoids in turmeric roots are a mixture of three main compounds: curcumin (~77%), demethoxycurcumin (~17%), and bisdemethoxycurcumin (~3%). Curcumin exists in two molecular configurations (known as tautomers): the bis-keto form is predominantly found in neutral and acidic conditions and in a solid phase, while the enolate form is predominately found in alkaline conditions.

Metabolism and Bioavailability

Clinical trials in humans indicate that the systemic bioavailability of orally administered curcumin is relatively low (3-5) and that mostly metabolites of curcumin, instead of curcumin itself, are detected in plasma or serum following oral consumption (6, 7). In the intestine and liver, curcumin is readily conjugated to form curcumin glucuronide and curcumin sulfate or, alternately, reduced to tetrahydrocurcumin, hexahydrocurcumin, and octahydrocurcumin (**Figure 2**) (4). An early clinical trial conducted in Taiwan indicated that serum curcumin concentrations peaked at 0.41 to 1.75 micromoles/liter (μM) one hour after oral doses of 4 to 8 g of curcumin (8). Another clinical trial conducted in the UK found that plasma concentrations of curcumin, curcumin sulfate, and curcumin glucuronide were in the range of 0.01 μM one hour after a 3.6 g oral dose of curcumin (9). Curcumin and its metabolites could not be detected in plasma at doses lower than 3.6 g/day. There is some evidence that orally administered curcumin accumulates in gastrointestinal tissues. For instance, when colorectal cancer patients took 3.6 g/day of curcumin orally for seven days prior to surgery, curcumin was detected in both malignant and normal colorectal tissue (10). In contrast, curcumin was not detected in the liver tissue of patients with liver metastases of colorectal cancer after the same oral dose of curcumin (11), suggesting that oral curcumin administration may not effectively deliver curcumin to tissues outside the gastrointestinal tract.

The safety and efficacy of several curcumin formulations are currently being explored in (pre)clinical settings with the aim of increasing the absorption, bioavailability, and tissue-targeted delivery of curcumin (12-16). Examples of approaches include conjugation to peptide carriers (e.g., to polylactic-co-glycolic acid [PLGA]); complexation with essential oils; coadministration with piperine; and encapsulation into nanoparticles, liposomes, phytosomes, polymeric micelles, and cyclodextrins (reviewed in 17).

Figure 2. Curcumin Metabolites



Biological Activities

Antioxidant activity

Curcumin is an effective scavenger of reactive oxygen species (ROS) and reactive nitrogen species in the test tube (18, 19). However, it is not clear whether curcumin acts as a direct antioxidant *in vivo*. Due to its limited oral bioavailability in humans (see Metabolism and Bioavailability), plasma and tissue curcumin concentrations are likely to be much lower than those of other fat-soluble antioxidants like α-tocopherol (vitamin E). Yet, curcumin taken orally may reach sufficient concentrations in the gastrointestinal tract and protect the intestinal mucosa against oxidative DNA damage (11). In addition to a potentially direct antioxidant activity, curcumin can induce the expression of phase II antioxidant enzymes, including glutamate-cysteine ligase (GCL), the rate-limiting enzyme in glutathione synthesis. Glutathione (GSH) is an important intracellular antioxidant that plays a critical role in cellular adaptation to stress (20). Curcumin was found to upregulate the expression of GCL through the activation of different signaling pathways (21). In particular, curcumin increases the expression of GCL and other detoxifying enzymes via the activation of the nuclear factor E2-related factor 2 (Nrf2)-dependent pathway.

Nrf2-dependent antioxidant pathway

Briefly, Nrf2 is a transcription factor that is bound to the protein Kelch-like ECH-associated protein 1 (Keap1) in the cytosol. Keap1 responds to oxidative stress signals by freeing Nrf2. Upon release, Nrf2 translocates to the nucleus and binds to the antioxidant response element (ARE) located in the promoter of genes coding for antioxidant/detoxifying enzymes and scavengers. Nrf2/ARE-dependent genes code for numerous mediators of the antioxidant response, including GCL, glutathione S-transferases (GSTs), thioredoxin, NAD(P)H quinone oxidoreductase 1 (NQO-1), and heme oxygenase 1 (HO-1) (22). Nrf2-dependent upregulation of HO-1 in curcumin-treated renal tubular epithelial cells challenged with high glucose concentrations was shown to prevent phenotype changes resembling fibrosis and known to occur at an early stage of diabetic renal injury (23). Curcumin also inhibited the progression of fibrosis in liver and lung in animal models of chronic inflammatory diseases (24, 25). Curcumin mitigated the effect of chronic ethanol intake on mouse liver, partly by upregulating Nrf2 target genes coding for NQO-1, HO-1, glutathione peroxidase (GSH-Px), and superoxide dismutase (SOD) (26). Curcumin treatment also counteracted oxidative damage induced by heavy ion irradiation by upregulating Nrf2 downstream genes for GCL, HO-1, NQO-1, and SOD in the brain of rats (27). Additional studies have demonstrated the ability of curcumin to reduce oxidative stress in different experimental settings via the induction of Nrf2/ARE pathway (reviewed in 22).

Anti-inflammatory activity

Curcumin has been shown to inhibit mediators of the inflammatory response, including cytokines, chemokines, adhesion molecules, growth factors, and enzymes like cyclooxygenase (COX), lipoxygenase (LOX), and inducible nitric oxide synthase (iNOS). Nuclear factor-kappa B (NF-κB) is a transcription factor that binds DNA and induces the transcription of the COX-2 gene, other pro-inflammatory genes, and genes involved in cell proliferation, adhesion, survival, and differentiation. The anti-inflammatory effects of curcumin result from its ability to inhibit the NF-κB pathway, as well as other pro-inflammatory pathways like the mitogen-activated protein kinase (MAPK)- and the Janus kinase (JAK)/Signal transducer and activator of transcription (STAT)-dependent signaling pathways (28). Inhibition of dextran sulfate sodium (DSS)-induced colitis by curcumin in mice has been associated with a downregulation of the expression of p38-MAPK and pro-inflammatory cytokine TNF-α and a reduction of myeloperoxidase (MPO) activity, a marker of neutrophil infiltration in intestinal mucosa (29). Curcumin has also been shown to improve colitis by preventing STAT3 activation and STAT3-dependent induction of cell proliferation in mouse colon (30). Moreover, curcumin was shown to attenuate the immune response triggered by collagen injections in a mouse model of rheumatoid arthritis, partly by blocking the proliferation of T lymphocytes in mouse splenocytes (31). In addition, curcumin has been found to reduce the secretion of TNF-α and IL-1β and the production of COX-2-induced prostaglandin G2. In one study, curcumin inhibited the secretion of matrix metalloproteins (MMPs) — responsible for the degradation of the synovial joints — in human fibroblast-like synoviocytes (31) and in human articular chondrocytes (32). Curcumin has also been found to alleviate neuro-inflammation in a mouse model of traumatic brain injury, reducing macrophage and microglial activation and increasing neuronal survival (33).

Anticancer activity

Effects on biotransformation enzymes

Some compounds are not carcinogenic until they are metabolized in the body by phase I biotransformation enzymes, such as enzymes of the cytochrome P450 (CYP) family (34). Primarily based on evidence from rodent studies, it is thought that curcumin may inhibit procarcinogen bioactivation and help prevent cancer by inhibiting the activity of multiple CYP enzymes in humans (35-37). Curcumin may also increase the activity of phase II detoxification enzymes, such as GSTs and quinone reductase (QR) (see also Nrf2-dependent antioxidant pathway) (35, 38, 39). However, it is important to note that the effect of curcumin on biotransformation enzymes may vary depending on the route of administration, the dose, and the animal model. In addition, curcumin intakes ranging from 0.45 to 3.6 g/day for up to four months did not increase leukocyte GST activity in humans (9).

Inhibition of proliferation and induction of apoptosis

Following DNA damage, the cell cycle can be transiently arrested to allow for DNA repair or for activation of pathways leading to programmed cell death (apoptosis) if the damage is irreparable (40). Defective cell-cycle regulation may result in the propagation of mutations that contribute to the development of cancer. Unlike normal cells, cancer cells proliferate rapidly and are unable to respond to cell death signals that initiate apoptosis. Curcumin has been found to induce cell-cycle arrest and apoptosis by regulating a variety of cell-signaling pathways (3, 41-45). For example, the inhibition of cell proliferation by curcumin has been associated with the Nrf2-dependent downregulation of DNA repair-specific flap endonuclease 1 (Fen1) in breast cancer cells in culture (46). Curcumin has been shown to induce p53-dependent or -independent apoptosis depending on the cancer cell type (47). In a panel of cancer cell lines, p53-independent apoptosis induced by curcumin was mediated by the rapid increase of ROS and the activation of MAPK and c-jun kinase (JNK) signaling cascades (48). Inhibition of NF-κB signaling by curcumin also suppresses proliferation and induces apoptosis in cancer cells (47).

Inhibition of tumor invasion and angiogenesis

Malignant and aggressive forms of cancer can invade surrounding tissues and spread to distant tissues once cancer cells have acquired the ability to leave the primary site (reduced cell-to-cell adhesion and loss of polarity), migrate, and disseminate. Epithelial-mesenchymal transition (EMT) is the process by which epithelial cells acquire the ability to migrate and invade through downregulating proteins like E-cadherin and γ-catenin and expressing mesenchymal markers like MMPs, N-cadherin, and vimentin. In breast cancer cells, curcumin prevented EMT-associated morphological changes induced by lipopolysaccharide (LPS) while upregulating E-cadherin and downregulating vimentin. It was further shown that curcumin inhibited NF-κB/Snail signaling involved in LPS-induced EMT (49). In another study, curcumin increased the expression of the small non-coding RNA miR181b, which then downregulated proinflammatory cytokines, CXCL1 and CXCL2, as well as MMPs, thereby reducing the metastatic potential of breast cancer cells. Curcumin inhibited IL-6-induced proliferation, migration, and invasiveness of human small cell lung cancer (SCLC) cells by reducing JAK/STAT3 phosphorylation (i.e., activation) and downstream genes coding for cyclin B1, survivin, Bcl-X$_L$, MMPs, intercellular adhesion molecule 1 (ICAM-1), and vascular endothelial growth factor (VEGF) (30).

Curcumin was found to exert its anticancer activities in many different types of cancer cells by regulating a variety of signaling pathways (reviewed in 2, 47).

Neuroprotective activity

In Alzheimer’s disease (AD), a peptide called β-amyloid (Aβ peptide) aggregates into oligomers and fibrils and forms deposits known as amyloid (or senile) plaques outside neurons in the hippocampus and cerebral cortex of patients. Another feature of AD is the accumulation of intracellular neurofibrillary tangles formed by phosphorylated Tau protein (50). Abnormal microglial activation, oxidative stress, and neuronal death are also associated with the progression of the disease. Curcumin has been found to inhibit Aβ fibril formation and extension and to destabilize preformed fibrils *in vitro* (51-53). Metal chelation by curcumin might interfere with metal ion (Cu^{2+}/Zn^{2+})-induced Aβ aggregation. Curcumin might also affect the trafficking of Aβ peptide precursor (APP) and the generation of Aβ peptides from APP (54, 55). Abnormally activated microglia and hypertrophic astrocytes around amyloid plaques in AD brains release cytotoxic molecules, such as proinflammatory cytokines and ROS, which enhance Aβ formation and deposition and further damage neurons. Curcumin was found to reduce the inflammatory response triggered by Aβ peptide-induced microglial activation and increase neuronal cell survival (56). When injected into the carotid artery of a transgenic mouse model of AD, curcumin was found to cross the blood-brain barrier, bind to amyloid plaques, and block the formation of Aβ oligomers and fibrils (53). In other animal models of AD, dietary curcumin decreased biomarkers of inflammation and oxidative damage, increased Aβ peptide clearance by macrophages, dismantled amyloid plaques in the brain, stimulated neuronal cell growth in the hippocampus, and improved Aβ-induced memory deficits (reviewed in 57).

Note: It is important to keep in mind that some of the biological activities discussed above were observed in cultured cells and animal models exposed to curcumin at concentrations unlikely to be achieved in cells of humans consuming curcumin orally (see Metabolism and Bioavailability).

Disease Prevention

Cancer

Oral curcumin administration has been found to inhibit the development of chemically-induced cancer in animal models of oral (58, 59), stomach (60, 61), liver (62), and colon (63-65) cancer. Apc$^{Min/+}$ mice have a mutation in the Apc (adenomatous polyposis coli) gene similar to that in humans with familial adenomatous polyposis, a genetic condition characterized by the development of numerous colorectal adenomas (polyps) and a high risk for colorectal cancer. Oral curcumin administration has been found to inhibit the development of intestinal adenomas in Apc$^{Min/+}$ mice (66, 67). Despite promising results in animal studies, there is presently little evidence that high intakes of curcumin or turmeric are associated with decreased cancer risk in humans. A 30-day phase II clinical trial in 40 smokers with at least eight rectal aberrant crypt foci (ACF; precancerous lesions) found that the number of ACF was significantly lower with a daily supplementation with 4 g/day of curcumin compared to 2 g/day (68). Several controlled clinical trials in humans designed to evaluate the effect of oral curcumin supplementation on precancerous colorectal lesions, such as adenomas, are under way (69).

Type 2 diabetes mellitus

Oxidative stress and inflammation have been implicated in the pathogenesis of type 2 diabetes mellitus and related vascular complications. A large body of preclinical evidence suggests that the antioxidant, anti-inflammatory, and glucose-lowering activities of curcumin and its analogs may be useful in the prevention and/or treatment of type 2 diabetes (70). In a nine-month, randomized, double-blind, placebo-controlled study in 237 subjects with impaired glucose tolerance (pre-diabetes), no progression to overt diabetes was reported with a daily ingestion of a mixture of curcuminoids (0.5 g), while 16.4% of placebo-treated participants developed diabetes (71). In addition, curcumin supplementation was shown to reduce insulin resistance and improve measures of pancreatic β-cell function and glucose tolerance. In an eight-week, randomized, placebo-controlled study in 67 individuals with type 2 diabetes, oral curcumin (a mixture of all three major curcuminoids; 0.6 g/day) failed to significantly lower the level of glycated hemoglobin A1c (HbA1c; a measure of glycemic control), plasma fasting glucose, total serum cholesterol, LDL-cholesterol, and serum triglycerides (72). Yet, supplemental curcumin was found to be as effective as lipid-lowering drug atorvastatin (10 mg/day) in reducing circulating markers of oxidative stress (malondialdehyde) and inflammation (endothelin-1, TNFα, IL-6) and in improving endothelial function. Another randomized controlled trial also reported that oral curcumin supplementation (1.5 g/day) for six months improved endothelial function, insulin sensitivity, and metabolic markers associated with atherogenesis (plasma triglycerides, visceral fat, total body fat) in participants with type 2 diabetes (73). Finally, in a two-month randomized, double-blind, placebo-controlled study in 40 individuals with type 2 diabetic nephropathy (kidney disease), daily curcumin ingestion (66.3 mg) significantly reduced urinary concentrations of proteins and inflammation markers (TGF-β, IL-8), suggesting that curcumin might be helpful with slowing the progression of kidney damage and preventing kidney failure (74). Larger trials are needed to assess whether curcumin could be useful in the prevention or management of type 2 diabetes and vascular complications.

Disease Treatment

Cancer

The ability of curcumin to regulate a variety of signaling pathways involved in cell growth, apoptosis, invasion, metastasis, and angiogenesis in preclinical studies elicited scientific interest in its potential as an anticancer agent in tumor therapy (75). To date, most of the controlled clinical trials of curcumin supplementation in cancer patients have been phase I trials, which are aimed at determining feasibility, tolerability, safety, and providing early evidence of efficacy (76). A phase I clinical trial in patients with advanced colorectal cancer found that doses up to 3.6 g/day for four months were well tolerated, although the systemic bioavailability of oral curcumin was low (77). When colorectal cancer patients with liver metastases took 3.6 g/day of curcumin orally for seven days, trace levels of curcumin metabolites were measured in liver tissue, but curcumin itself was not detected (11). In contrast, curcumin was measurable in normal and malignant colorectal tissue after patients with advanced colorectal cancer took 3.6 g/day of curcumin orally for seven days (10). In a pilot trial in patients awaiting gastrointestinal endoscopy or colorectal cancer resection, the administration of a mixture of three major curcuminoids (2.35 g/day for 14 days) resulted in detectable amounts of curcumin in colonic mucosa (mean concentration, 48.4 μg/g of tissue), demethoxycurcumin (7.1 μg/g), and bisdemethoxycurcumin (0.7 μg/g) (78).

While these findings suggested that oral curcumin may likely be more effective as a therapeutic agent in cancers of the gastrointestinal tract than of other tissues, some phase I/II trials have also examined whether supplemental curcumin may confer additional benefits to conventional drugs against different types of cancer. Combining curcumin with anticancer drugs like gemcitabine in pancreatic cancer (79, 80), docetaxel in breast cancer (81), and imatinib in chronic myeloid leukemia (82) may be safe and well tolerated. A recent single-arm, phase II trial combining three cycles of docetaxel/prednisone and curcumin (6 g/day) was carried out in 26 patients with castration-resistant prostate cancer (83). The level of prostate-specific antigen (PSA) was decreased in most patients and was normalized in 36% of them, and the co-administration of curcumin with drugs showed no toxicity beyond adverse effects already related to docetaxel monotherapy. Many registered phase I/II clinical trials designed to investigate the effectiveness of curcumin alone or with first-line treatment in patients with breast, prostate, pancreatic, lung, or colorectal cancer are under way (69).

Inflammatory diseases

Although curcumin has been demonstrated to have anti-inflammatory and antioxidant activities in cell culture and animal studies, few randomized controlled trials have examined the efficacy of curcumin in the treatment of inflammatory conditions. A placebo-controlled trial in 40 men who had surgery to repair an inguinal hernia or hydrocele found that oral curcumin supplementation (1.2 g/day) for five days was more effective than placebo in reducing post-surgical edema, tenderness and pain, and was comparable to phenylbutazone therapy (300 mg/day) (84).

Rheumatoid arthritis

A preliminary intervention trial that compared curcumin with a nonsteroidal anti-inflammatory drug (NSAID) in 18 patients with rheumatoid arthritis (RA) found that improvements in morning stiffness, walking time, and joint swelling after two weeks of curcumin supplementation (1.2 g/day) were comparable to those experienced after two weeks of phenylbutazone (NSAID) therapy (300 mg/day) (85). In a more recent randomized, open-label study in 45 RA patients, supplementation with a mixture of all three major curcuminoids (0.5 g/day for eight weeks) was found to be as effective as diclofenac (NSAID; 50 mg/day) in reducing measures of disease activity, tenderness, and swelling joints (86). Larger randomized controlled trials are needed to determine whether oral curcumin supplementation is effective in the treatment of RA.

Radiation dermatitis

Radiation-induced skin inflammation occurs in most patients receiving radiation therapy for sarcoma, lung, breast, or head and neck cancer. One randomized, double-blind, placebo-controlled trial in 30 women prescribed radiation therapy for breast carcinoma *in situ* reported a reduction of radiation-induced dermatitis severity and moist desquamation with a supplemental curcuminoid mixture (6 g/day for four to seven weeks). Curcumin failed to reduce skin redness and radiation-induced pain at the site of treatment (87).

Ulcerative colitis

Ulcerative colitis (UC) is a long-term condition characterized by diffuse and superficial inflammation of the colonic mucosa. Disease activity may fluctuate between periods of remission and periods of relapse. Preliminary evidence suggests that curcumin might be useful as an add-on therapy to control disease activity. One multicenter, randomized, double-blind, placebo-controlled study has examined the efficacy of curcumin enema (2 g/day) in the prevention of relapse in 82 patients with quiescent UC (88). Six-month treatment with curcumin significantly reduced measures of disease activity and severity and resulted in a lower relapse rate than with placebo in subjects on standard-of-care medication (sulfasalazine or mesalamine); yet, there was no difference in the proportion of patients who experienced relapse six months after curcumin was discontinued (88). In another randomized controlled trial in active UC patients treated with mesalamine, the percentage of patients in clinical remission was significantly higher after a one-month treatment with oral curcumin (3 g/day) than with placebo (89). Larger trials are needed to ensure that curcumin can be safely used with conventional UC treatments and to further support its potential therapeutic benefits for relapsing-remitting UC.

Oral health

Emerging evidence suggests that curcumin has anti-inflammatory and antimicrobial properties that could be beneficial in the treatment of certain diseases of the oral cavity. For example, the topical application of a curcumin gel was found to reduce gingival bleeding and periodontal bacteria after conventional periodontal therapy (scaling and root planing) (90-92). A mouthwash containing curcumin was also found to be as effective as chlorhexidine in reducing inflammation in individuals who underwent periodontal therapy for gingivitis (93).

Oral submucous fibrosis

Any part of the oral cavity may be affected by oral submucous fibrosis (OSMF), a currently incurable condition especially prevalent in Southeast Asia and India. OSMF is characterized by the formation of excess fibrous tissue (fibrosis) that leads to stiffness of the mucosa and restricted mouth opening. A few recent intervention studies showed that curcumin could improve some symptoms, such as burning sensations and reduced mouth opening (reviewed in 94). In an open-label intervention study in 40 OSMF patients randomized to receive either the conventional treatment (weekly intra-lesional injections of steroids) or daily oral administration of a *Curcuma longa* Linn extract (600 mg/day) for three months, the burning sensation significantly improved in the curcumin-treated group, while tongue protrusion was reduced with conventional therapy. No differences between the two treatment groups were seen with respect to mouth opening (95). A six-month follow-up of the effect of oral curcumin (2 g/day) in OSMF patients treated for three months found that curcumin outperformed steroid ointment in its ability to increase maximum mouth opening and to reduce self-reported burning sensation (96). Further studies should assess the appropriate dose of curcumin to achieve the greatest benefits and determine whether curcumin can enhance the effect of standard-of-care treatment in limiting OSMF disease progression.

Cognitive decline and Alzheimer’s disease

Alzheimer’s disease (AD) is a form of dementia characterized by extracellular deposition of β-amyloid plaques, intracellular formation of neurofibrillary tangles, and neuronal loss, eventually leading to brain atrophy and cognitive impairment in affected individuals (57). When injected into the carotid artery, curcumin was found to cross the blood-brain barrier in an animal model of AD (53), though it is not known whether curcumin taken orally can reach the blood-brain barrier at sufficient concentrations and impede cognitive decline in humans. As a result of promising findings in animal models (see Neuroprotective activity), a few recent clinical trials have examined the effect of oral curcumin supplementation on cognition in healthy older adults and AD patients (57). A randomized, double-blind, placebo-controlled trial in 60 healthy older adults (mean age, 68.5 years) investigated whether acute (80 mg) or chronic (80 mg/day for 4 weeks) oral intake of curcumin could improve their ability to cope with the mental stress and change in mood usually associated with undergoing a battery of cognitive tests (97). A significant reduction in mental fatigue and higher levels of calmness and contentedness following cognitive test sessions were observed in individuals who consumed curcumin (either acutely or chronically) compared to the placebo group. Additionally, the results of cognitive ability tests suggested that curcumin treatment had limited benefits on cognitive function, as shown by better scores in measures of sustained attention and working memory compared to placebo (97).

The results of a six-month trial in 27 patients with AD found that oral supplementation with up to 4 g/day of curcumin — containing all three major curcuminoids — was safe (6). Yet, measures of cognitive performance (using the Mini Mental State Examination [MMSE] scoring scale) and levels of F$_2$-isoprostanes (oxidative stress markers) and antioxidants in blood were not found to be significantly different between curcumin- and placebo-treated subjects at the end of the intervention period. In another six-month, randomized, double-blind, placebo-controlled study of subjects with mild-to-moderate AD, curcumin failed to improve cognitive test scores and to reduce blood and cerebrospinal fluid (CSF) concentrations of β-amyloid peptide, CSF concentrations of total and phosphorylated Tau protein, and CSF concentrations of F$_2$-isoprostanes (98).

Despite the lack of encouraging results from completed trials, several randomized controlled studies are under way to determine whether supplemental curcumin has the ability to reverse or prevent cognitive deficits in both healthy and cognitively impaired individuals (57).

Major depressive disorder

Major depressive disorder (MDD) is a neuropsychiatric disorder associated with abnormal neurotransmission; it is primarily treated with drugs that improve the bioavailability of neurotransmitters like serotonin, noradrenaline, and dopamine in the brain (99). Characteristics of MDD also include alterations in the hypothalamus-pituitary-adrenal axis, increased neuroinflammation, defective neurogenesis, and neuronal death.

A few clinical studies have examined the effect of curcumin alone or with conventional antidepressant drugs in MDD patients. A recent meta-analysis of six randomized controlled trials found that supplementation with curcumin significantly reduced depression symptoms (100). However, in one of the studies included in this meta-analysis — a double-blind, controlled study in 56 adults diagnosed with MDD — curcumin treatment (~880 mg/day of curcuminoids) for eight weeks was no more effective than placebo in reducing self-reported depression- and anxiety-related symptoms (101). Significant improvements in the severity and frequency of specific depression-related symptoms only occurred after four weeks of treatment, suggesting that a longer treatment period might be needed to uncover the antidepressant effects of curcumin (100, 101). In another randomized, placebo-controlled trial, supplemental curcumin (330 mg/day) for five weeks failed to relieve depressive symptoms in patients treated with conventional antidepressants (102). In contrast, in a six-week, randomized, single-blinded, placebo-controlled study in 60 MDD patients, supplemental curcumin (~880 mg/day of curcuminoids) alone yielded a similar response rate to the antidepressant, fluoxetine (a serotonin reuptake inhibitor [Prozac]; 20 mg/day) in terms of depressive symptoms; no additional effect was observed when both curcumin and fluoxetine treatments were combined (103). Moreover, in a randomized controlled study in 100 participants taking escitalopram (a serotonin reuptake inhibitor [Lexapro]; 5 to 15 mg/week), supplemental curcumin (1,000 mg/day) for six weeks increased the antidepressant effect of the medication (104). Curcumin also induced a reduction in plasma concentrations of inflammatory markers and an increase in plasma concentrations of brain-derived neurotrophic factor compared to placebo (antidepressant drug alone) (104).

Larger clinical trials are needed to address the long-term effect of curcumin in subjects with major depression.

Premenstrual syndrome

Premenstrual syndrome (PMS) refers to a range of emotional (e.g., irritability, anxiety), behavioral (e.g., fatigue, insomnia), and physical symptoms (e.g., breast tenderness, headache) occurring prior to the monthly menstrual period in up to 90% of premenopausal women. In a recent randomized, double-blind, placebo-controlled trial in 70 women with PMS, the daily supplementation with 0.2 g of curcumin for 10 days during three consecutive menstrual cycles significantly reduced overall PMS severity, as assessed by a composite measure of all emotional, behavioral, and physical symptoms (105). Additional trials are necessary to evaluate the efficacy of curcumin in the management of PMS.

Sources

Food sources

Turmeric is the dried ground rhizome of *Curcuma longa* Linn (106). It is used as a spice in Indian, Southeast Asian, and Middle Eastern cuisines. Curcuminoids comprise about 2%-9% of turmeric (107). Curcumin is the most abundant curcuminoid in turmeric, providing about 75% of the total curcuminoids, while demethoxycurcumin and bisdemethoxycurcumin generally represent 10%-20% and less than 5% of the total curcuminoids, respectively (108). Curry powder contains turmeric along with other spices, but the amount of curcumin in curry powders is variable and often relatively low (109). Curcumin extracts are also used as food-coloring agents (110).

Supplements

Commercial curcumin is usually a mixture of curcumin, demethoxycurcumin, and bisdemethoxycurcumin (see **Figure 1** above). Curcuminoid extracts are available as dietary supplements without a prescription in the US. The labels of a number of these extracts state that they are standardized to contain 95% curcuminoids, although such claims are not strictly regulated by the US Food and Drug Administration (FDA). Some curcumin preparations also contain piperine, which may increase the bioavailability of curcumin by inhibiting its metabolism (108). However, piperine may also affect the metabolism of drugs (see Drug interactions). Optimal doses of curcumin for cancer chemoprevention or therapeutic uses have not been established. It is unclear whether doses less than 3.6 g/day are biologically active in humans (see Metabolism and Bioavailability). Curcuminoid-containing supplements taken on an empty stomach may cause gastritis and peptic ulcer disease (108).

Safety

Adverse effects

In the United States, turmeric is generally recognized as safe (GRAS) by the FDA as a food additive (110). An increase in gallbladder contractions was observed in 12 healthy people supplemented with single doses of 20 to 40 mg of curcumin (111, 112). Yet, serious adverse effects have not been reported in humans taking high doses of curcumin. A dose escalation trial in 24 adults found that single oral dosages up to 12 g were safe, and adverse effects, including diarrhea, headache, rash, yellow stool, were not related to dose (7). In a phase I trial in Taiwan, curcumin supplementation up to 8 g/day for three months was reported to be well tolerated in patients with precancerous conditions or noninvasive cancer (8). Another clinical trial in the UK found that curcumin supplementation ranging from 0.45 to 3.6 g/day for four months was generally well tolerated by people with advanced colorectal cancer, although two participants experienced diarrhea and another reported nausea (9). Increases in serum alkaline phosphatase and lactate dehydrogenase were also observed in several participants, but it was not clear whether these increases were related to curcumin supplementation or cancer progression (3). In an open-label phase II trial, curcumin treatment (8 g/day) in combination with the anticancer drug gemcitabine was associated with severe abdominal pain in 7 out of 17 patients with advanced pancreatic cancer, leading to the treatment being discontinued in five patients while curcumin dosage was reduced to 4 g/day in two patients (79).

Pregnancy and lactation

Although there is no evidence that dietary consumption of turmeric as a spice adversely affects pregnancy or lactation, the safety of curcumin supplements in pregnancy and lactation has not been established.

Drug interactions

Curcumin has been found to inhibit platelet aggregation *in vitro* (113, 114), suggesting a potential for curcumin supplementation to increase the risk of bleeding in people taking anticoagulant or antiplatelet medications, such as aspirin, clopidogrel (Plavix), dalteparin (Fragmin), enoxaparin (Lovenox), heparin, ticlopidine (Ticlid), and warfarin (Coumadin). In cultured breast cancer cells, curcumin inhibited apoptosis induced by the chemotherapeutic agents, camptothecin, mechlorethamine, and doxorubicin at concentrations of 1 to 10 μM (115). In an animal model of breast cancer, dietary curcumin inhibited cyclophosphamide-induced tumor regression. Yet, it is not known whether oral curcumin administration will result in breast tissue concentrations that are high enough to inhibit cancer chemotherapeutic agents in humans (11). Curcuminoids may interfere with the activity of efflux drug transporters of the ATP-binding cassette (ABC) family, including P-glycoprotein, multidrug resistance protein (MRP), and breast cancer-resistant protein (BCRP), which function as ATP-dependent efflux pumps that actively regulate the excretion of a number of drugs limiting their systemic bioavailability (116, 117). Curcumin was also found to affect the activity of phase I biotransformation enzymes like cytochrome P450 (CYP) 3A4 (CYP3A4) (118), which catalyzes the metabolism of about one-half of all marketed drugs in the US (119). In healthy Japanese volunteers, curcumin (2 g) was found to increase plasma sulfasalazine concentration following the administration of a therapeutic dose (2 g) of the anti-rheumatic drug sulfasalazine (Salazopyrin, Azulfidine) (120).

Some curcumin supplements also contain piperine to increase the bioavailability of curcumin. Piperine may also interfere with efflux drug transporters and phase I cytochrome P450 enzymes and increase the bioavailability and slow the elimination of a number of drugs, including phenytoin (Dilantin), propranolol (Inderal), theophylline, and carbamazepine (Tegretol) (121-123).

Summary

- Flavonoids are a large family of polyphenolic plant compounds. Six major subclasses of flavonoids, namely anthocyanidins, flavan-3-ols, flavonols, flavanones, flavones, and isoflavones, flavonols are the most widespread in the human diet. *(More information)*
- Dietary flavonoids are naturally occurring in fruit, vegetables, chocolate, and beverages like wine and tea. There has been much interest in the potential health benefits of flavonoids associated with fruit- and vegetable-rich diets. *(More information)*
- The physicochemical properties of flavonoids influence their metabolic fate, i.e., their digestion, absorption, and biotransformation. The bioavailability of these polyphenols *in vivo* is a major determinant in their ability to exert biological activities relevant to human health. *(More information)*
- Many of the biological effects of flavonoids appear to be related to their ability to modulate a number of cell-signaling cascades. Flavonoids have been shown to exhibit antiinflammatory, antithrombogenic, antidiabetic, anticancer, and neuroprotective activities through different mechanisms of action *in vitro* and in animal models. *(More information)*
- Accumulating evidence from randomized controlled trials suggests that consumption of flavan-3-ols and anthocyanidins can be beneficial for metabolic and cardiovascular health. *(More information)*
- The results of small-scale randomized controlled trials suggest that consumption of flavonoid-rich food and beverages containing anthocyanins or flavan-3-ols may improve vascular endothelial function. As yet, it is not known whether these acute improvements result in long-term reductions in risk of cardiovascular disease. *(More information)*
- Promising findings in randomized controlled studies indicate that supplementation with flavan-3-ols or anthocyanidins may improve glycemic control in subjects at-risk or diagnosed with type 2 diabetes mellitus. *(More information)*
- Despite promising results in animal studies, only a limited number of observational studies have reported potential cancer preventive effects of flavonoids in humans. Higher intakes of soy isoflavones may be associated with reduced risks of breast cancer in postmenopausal women and prostate cancer in men. *(More information)*
- Evidence suggesting that some flavonoids or flavonoid-rich foods may enhance cognitive function is currently limited, and it is not yet known whether their consumption could lower the risk of cognitive impairments and dementia in humans. *(More information)*
- High intakes of dietary flavonoids are generally regarded as safe, especially because of their low bioavailability. However, flavonoid supplements may affect the action of anticoagulants and increase the toxicity of a wide range of drugs when taken concurrently. *(More information)*

Introduction

Flavonoids are a large family of over 5,000 hydroxylated polyphenolic compounds that carry out important functions in plants, including attracting pollinating insects; combating environmental stresses, such as microbial infection; and regulating cell growth (1). Their bioavailability and biological activities in humans appear to be strongly influenced by their chemical nature. Since the 1990s, there has been a growing interest in dietary flavonoids due to their likely contribution to the health benefits of fruit- and vegetable-rich diets. This article reviews some of the scientific evidence regarding the role of dietary flavonoids in health promotion and disease prevention in humans; it is not meant to be a comprehensive review on every health topic studied.

Flavonoid Subclasses

Flavonoids are classified into 12 major subclasses based on chemical structures, six of which, namely anthocyanidins, flavan-3-ols, flavonols, flavones, flavanones, and isoflavones (**Table 1** and **Figures 1-9**) are of dietary significance. Glycosylated flavonols (bound to at least one sugar molecule) are the most widely distributed flavonoids in the diet (2, 3).

Table 1. Common Dietary Flavonoids
(Select the highlighted text to see chemical structures.)

Flavonoid Subclass	Dietary Flavonoids (aglycones)	Some Common Food Sources (see also Sources)
Anthocyanidins*	Cyanidin, Delphinidin, Malvidin, Pelargonidin, Peonidin, Petunidin	Red, blue, and purple berries; red and purple grapes; red wine
Flavan-3-ols	*Monomers (Catechins)*: (+)-Catechin, (-)-Epicatechin, (-)-Epigallocatechin, (+)-Gallocatechin; and their gallate derivatives	Teas (particularly white, green, and oolong), cocoa-based products, grapes, berries, apples
	Dimers and Polymers: Proanthocyanidins#	Apples, berries, cocoa-based products, red grapes, red wine
	Theaflavins, Thearubigins	Black tea
Flavonols	Isorhamnetin, Kaempferol, Myricetin, Quercetin	Onions, scallions, kale, broccoli, apples, berries, teas
Flavones	Apigenin, Luteolin, Baicalein, Chrysin	Parsley, thyme, celery, hot peppers
Flavanones	Eriodictyol, Hesperetin, Naringenin	Citrus fruit and juices, e.g., oranges, grapefruits, lemons
Isoflavones	Daidzein, Genistein, Glycitein, Biochanin A, Formononetin	Soybeans, soy foods, legumes
*Anthocyanidins with one or more sugar moieties (anthocyanidin glycosides) are called anthocyanins. #Proanthocyanidin oligomers formed from (+)-catechin and (-)-epicatechin subunits are called procyanidins.		

For more detailed information on the health effects of isoflavones, a subclass of flavonoids with estrogenic activity, see the article on Soy Isoflavones.

For more information on the health benefits of foods that are rich in flavonoids, see the articles on Fruit and Vegetables, Legumes, and Tea.

prodelphinidin B-type dimer

Metabolism and Bioavailability

The amount of flavonoids present in ingested food has little importance unless dietary flavonoids are absorbed and become available to target tissues within the body. During and after intestinal absorption, flavonoids are rapidly and extensively metabolized in intestinal and liver cells such that they are likely to appear as metabolites (e.g., phase II metabolites) in the bloodstream and urine (4). Additionally, the biological activities of flavonoid metabolites are likely to be different from those of their parent compounds (5). Some of the factors influencing the metabolic fate and bioavailability of dietary flavonoids are mentioned below.

Chemical structure of flavonoids

Most flavonoids occur in edible plants and foods as β-glycosides, i.e., bound to one or more sugar molecules (6). Exceptions include flavan-3-ols (catechins and proanthocyanidins) and fermented soy-based products that are exposed to microbial β-glucosidases, which catalyze the release of sugar molecules from glycosylated isoflavones (7). Even after food processing and cooking, most flavonoid glycosides reach the small intestine intact. Only flavonoid aglycones (not bound to a sugar molecule) and a few flavonoid glucosides (bound to glucose) are easily absorbed in the small intestine (8). Glycosylated flavonoids might be able to penetrate the mucus layer of the intestine and be deglycosylated on the cell surface before absorption. Those that cannot be deglycosylated in the small intestine may be hydrolyzed by bacterial enzymes in the colon (7). Nevertheless, colonic bacteria might remove sugar moieties and rapidly degrade aglycone flavonoids, thus limiting their absorption in the colon (9).

In contrast to monomeric flavan-3-ols (catechins), the polymeric nature of proanthocyanidins likely prevents their intestinal absorption. Flavan-3-ol monomers and procyanidins are transformed by the intestinal microbiota to 5-(hydroxyphenyl)-γ-valerolactones which appear in the circulatory system and are excreted in urine as sulfate and glucuronide metabolites (**Figure 10**). Valerolactones may be further degraded by the colonic microbiota to smaller phenolic acids and aromatic compounds. The colonic microbiota also metabolize the gallate esters of flavonoids, generating gallate, which is further catabolized to pyrogallol. Microbe-derived flavonoid metabolites are readily absorbed into the circulatory system and excreted in both free forms and as phase II metabolites in urine (9).

Figure 10. Chemical Structures of Some Flavan-3-ol Metabolites

Interactions with food matrix

The presence of macronutrients in food influences the bioavailability of co-ingested flavonoids (reviewed in 8, 10, 11). The binding affinity and potential (non-) covalent interactions of flavonoids with food proteins, carbohydrates, and fats are directly associated with the physicochemical properties of flavonoids (reviewed in 8). Proteins in milk might reduce the absorption of polyphenols from cocoa or black tea. The presence of milk proteins bound to flavonoids was shown to weaken the flavonoid antioxidant capacity *in vitro* (12), and milk consumption has been shown to blunt the vascular benefits of tea flavonoids in healthy volunteers (13). Some carbohydrate-rich foods may increase the deglycosylation and absorption of flavonoids by stimulating gastrointestinal motility, mucosal blood flow, and colonic fermentation. Conversely, dietary flavonoids have been shown to interfere with carbohydrate digestion and absorption (see Biological Activities).

Composition of gut microbiota

In the large intestine, gut microbial enzymes transform flavonoids through deglycosylation, ring fission, dehydroxylation, demethylation, etc. into metabolites that can then be absorbed or excreted (9, 14). The diversity and activity of colonic bacteria, which are partly dependent on a person's dietary habits, will determine which metabolites can be produced from ingested flavonoids (15, 16). The composition of the colonic microbiota can therefore affect the metabolic fate and bioavailability of dietary flavonoids (17).

The detoxification pathway

Flavonoids are recognized as xenobiotics by the body such that they undergo extensive modifications first in the intestinal mucosa and then in the liver.

Phase II enzymes

Depending on their structural characteristics, flavonoids can be rapidly transformed by phase II detoxification enzymes to form methylated, glucuronidated, and/or sulfated metabolites (2). This metabolic pathway increases the solubility of phenolic aglycones and facilitates their excretion in the bile and urine (11). Free (unconjugated) aglycones are generally absent from the bloodstream, with the possible exception of trace levels of catechins (17). Catechol-*O*-methyltransferase (COMT) is the detoxifying enzyme responsible for the methylation of the hydroxyl groups of flavonoids, producing *O*-methylated flavonoids. A single nucleotide polymorphism (SNP) in the gene for COMT — known as SNP rs4680 G>A — causes a valine-to-methionine substitution in the sequence of the enzyme. Individuals with the A/A genotype have a form of the enzyme that is three- to four-fold less active than the wild-type variant in G/G genotype carriers (18). It has been suggested that subjects who are less efficient at eliminating green tea flavonoids may be more likely to benefit from their consumption (19).

Efflux transporters

Flavonoid conjugates are excreted via the action of efflux transporters from the ATP-binding cassette (ABC) family, including P-glycoprotein, MRPs (multidrug resistance proteins), or BCRPs (breast cancer-resistant proteins). Depending on their physicochemical properties, some flavonoids may interfere with the activity of ABC transporters (20). This implies that flavonoids can affect their own bioavailability, as well as that of other substrates of these transporters (e.g., pharmacological drugs) (see Drug interactions).

Binding to plasma proteins

Flavonoid bioavailability may be inversely related to their binding affinity to plasma proteins (21). Greater binding affinity to plasma proteins (and thus, possibly, lower flavonoid bioavailability) has been linked to structural characteristics, such as methylation and galloylation. On the contrary, glycosylation reduced binding affinity to plasma proteins, suggesting that aglycones might have a limited bioavailability compared to glycosylated flavonoids. While glucuronidation is thought to facilitate the excretion of flavonoids from the body, glucuronides show little affinity to plasma proteins and might thus be able to diffuse to target tissues where deglucuronidation can take place (8).

Summary

In general, the bioavailability of flavonoids is low due to limited absorption, extensive metabolism, and rapid excretion. Isoflavones are thought to be the most bioavailable of all flavonoid subclasses, while anthocyanins and galloylated catechins are very poorly absorbed (8, 22). Yet, given the wide variability in structures within subclasses, it is difficult to generalize the absorbability and bioavailability of flavonoids based only on their structural classification. In addition, when evaluating the data from flavonoid research in cultured cells, it is important to consider whether the flavonoid concentrations and metabolites used are physiologically relevant (23). In humans, peak plasma concentrations of soy isoflavones and citrus flavanones have not been found to exceed 10 micromoles/liter (μM) after oral consumption. Peak plasma concentrations measured after the consumption of anthocyanins, flavan-3-ols, and flavonols (including those from tea) are generally lower than 1 μM (2). A recent quantitative analysis of 88 polyphenolic metabolites (not limited to flavonoids) identified in human blood and urine found median peak concentrations of 0.9 μM and 3.2 μM after food intake and oral supplementation, respectively (4).

Biological Activities

Direct antioxidant activity

Flavonoids are effective scavengers of free radicals in the test tube (*in vitro*) (24, 25). However, even with very high flavonoid intakes, plasma and intracellular flavonoid concentrations in humans are likely to be 100 to 1,000 times lower than concentrations of other antioxidants, such as ascorbate (vitamin C), uric acid, and glutathione. Moreover, most circulating flavonoids are actually flavonoid metabolites, some of which have lower antioxidant activity than the parent flavonoid (5). For these reasons, the relative contribution of dietary flavonoids to plasma and tissue antioxidant function *in vivo* is likely to be very small or negligible (26-28).

Metal chelation

Metal ions, such as iron and copper, can catalyze the production of free radicals. The ability of flavonoids to chelate (bind) metal ions appears to contribute to their antioxidant activity *in vitro* (29, 30). In living organisms, most iron and copper are bound to proteins, limiting their participation in reactions that produce free radicals. Although the metal-chelating activities of flavonoids may be beneficial in pathological conditions of iron or copper excess, it is not known whether flavonoids or their metabolites function as effective metal chelators *in vivo* (26).

Effects on cell-signaling pathways

Cells are capable of responding to a variety of different stresses or signals by increasing or decreasing the availability of specific proteins. The complex cascades of events that lead to changes in the expression of specific genes are known as cell-signaling pathways or signal transduction pathways. These pathways regulate numerous cell processes, such as proliferation, differentiation, inflammatory responses, apoptosis (programmed cell death), and survival. Although it was initially hypothesized that the biological effects of flavonoids would be related to their antioxidant activity, available evidence from cell culture experiments suggests that many of the effects of flavonoids, including antiinflammatory, antidiabetic, anticancer, and neuroprotective activities, are related to their ability to modulate cell-signaling pathways (27). Intracellular concentrations of flavonoids required to affect cellular signaling are considerably lower than those required to affect cellular antioxidant capacity. Flavonoid metabolites may retain their ability to interact with cell-signaling proteins even if their antioxidant activity is diminished (31, 32).

Effective signal transduction requires proteins known as kinases that catalyze the phosphorylation of target proteins, which become either activated or inhibited. Cascades involving specific phosphorylations or dephosphorylations of signal transduction proteins ultimately affect the activity of transcription factors — proteins that bind to specific response elements on DNA and promote or prevent the transcription of target genes. Results of numerous studies in cell culture suggest that flavonoids may affect chronic disease by selectively inhibiting kinases (27, 33). Cell growth and proliferation are also regulated by growth factors that initiate cell-signaling cascades by binding to specific receptors in cell membranes. Flavonoids may alter growth factor signaling by inhibiting receptor phosphorylation or blocking receptor binding by growth factors (34).

Each flavonoid subclass contains many types of chemicals with varying biological activities (and potential health benefits) such that the activity of a specific flavonoid cannot easily be generalized. Some examples of major biological activities of flavonoids are highlighted below.

Biological activities related to the prevention of cardiovascular disease

Flavonoids have been shown to (1) reduce inflammation by suppressing the expression of pro-inflammatory mediators (35-37); (2) down-regulate the expression of vascular cell adhesion molecules, which contribute to the recruitment of inflammatory white blood cells from the blood to the arterial wall (38, 39); (3) increase the production of nitric oxide (NO) by endothelial nitric oxide synthase (eNOS), thus improving vascular endothelial function (40); (4) inhibit angiotensin-converting enzyme, thus inducing vascular relaxation (41); (5) inhibit platelet aggregation (42); and (6) oppose smooth muscle cell proliferation and migration occurring during atherogenesis (43).

Biological activities related to the prevention of diabetes

Flavonoids have been found to interfere with the digestion, absorption, and metabolism of carbohydrates (reviewed in 44). Each subclass of flavonoids has also demonstrated anti-diabetic properties, including (1) improving insulin secretion and viability of pancreatic β-cells under glucotoxic or pro-inflammatory conditions, (2) increasing insulin-stimulated glucose uptake by target cells, (3) protecting muscle cells against fatty acid-induced insulin resistance, and (4) reducing hyperglycemia and improving glucose tolerance in animal models of obesity and/or type 2 diabetes mellitus (45).

Biological activities related to the prevention of cancer

Flavonoids have been found to (1) scavenge free radicals that can damage macromolecules, including DNA (46, 47); (2) interfere with biotransformation enzymes and efflux transporters, possibly preventing the activation of procarcinogenic chemicals and promoting their excretion from the body (48, 49); (3) regulate proliferation, DNA repair, or activation of pathways leading to apoptosis (programmed cell death) in case of irreversible DNA damage (50); and (4) inhibit tumor invasion and angiogenesis (51, 52).

Biological activities related to neuroprotection and cognitive function

Flavonoids are thought to (1) promote neurogenesis, synaptic growth, and neuron survival in the learning and memory-related brain regions (e.g., hippocampus) by stimulating the production of neurotrophins like BDNF; (2) protect hippocampal cells and striatal dopaminergic cells from cytotoxic molecules (pro-inflammatory mediators and ROS) released by abnormally activated microglia and hypertrophic astrocytes in neurodegenerative disorders; (3) reduce neuroinflammation by inhibiting the generation of pro-inflammatory cytokines, lipid mediators, and reactive oxygen species by astrocytes and microglial cells; (4) stimulate the production of nitric oxide (NO), which improves endothelial function, increases cerebral blood flow, and protects artery walls against the buildup of atherosclerotic plaques (reviewed in 53, 54).

Disease Prevention

Cardiovascular disease

Several prospective cohort studies conducted in the US and Europe have examined the relationship between some measure of dietary flavonoid intake and cardiovascular disease (CVD) or mortality. A recent meta-analysis of 14 prospective studies published between 1996 and 2012 reported that higher intakes in each flavonoid subclass were significantly associated with a reduced risk of cardiovascular events (55). Top versus bottom quantiles of intake for each of the flavonoid subclasses were associated with an approximate 10% reduction in the risk of CVD. Another meta-analysis of eight prospective studies found a 14% reduced risk of stroke with the highest versus lowest quintile of flavonol intakes (56). However, several serious limitations highlighted in a recent publication by Jacques et al. suggested caution when interpreting these results (57). In particular, most of the prospective studies in these meta-analyses did not include all flavonoid subclasses nor calculate intakes using the latest and more complete versions of the USDA databases for the flavonoid content of foods (58-60). Another major concern is the lack of adjustment regarding the overall quality of the diet. Consumers with higher flavonoid intakes are likely to have a greater consumption of fruit and vegetables and overall healthier diets than those with poor flavonoid intakes. Additionally, none of the studies excluded potential bias due to constituents of flavonoid-rich foods that are known to either lower (e.g., other phytochemicals, vitamins, dietary fiber) or increase (e.g., sodium, saturated fat) the risk of cardiovascular events (discussed in 57).

In the Framingham Offspring Cohort study that followed 2,880 adults for a mean of 14.9 years, consumption of all flavonoid subclasses except flavones and flavanones was inversely associated with CVD (57). Yet, adjusting for confounding factors, including fruit and vegetable intake and overall diet quality, attenuated these relationships such that they were no longer statistically significant. An analysis of a larger prospective study of the EPIC-Norfolk cohort (24,885 participants) that considered confounding by many dietary factors (vitamin C, dietary fiber, fat, saturated fat, potassium, sodium, and alcohol) found no significant association between flavan-3-ol intake and CVD-related or all-cause mortality (61).

A number of large prospective studies and small-scale, randomized controlled trials have investigated the effects of flavonoids on established biomarkers of CVD, including those involved in oxidative stress, inflammation, abnormal blood lipid profile, endothelial dysfunction, and hypertension; some of these studies are highlighted below.

Biochemical markers of cardiovascular disease

In a cross-sectional analysis of the Framingham Offspring Cohort study, the highest versus lowest intake of anthocyanins (≤3.5 mg/day versus ≥23.5 mg/day) was associated with lower concentrations of acute-phase reactant proteins (-100%), pro-inflammatory cytokines (-75%), and markers of oxidative stress (-52%), even after adjustment for confounding variables (62). Interestingly, a food-based analysis revealed that intakes of foods rich in anthocyanins, e.g., apples, red wine, and strawberries, were also inversely associated with an overall inflammation score based on 12 different biomarkers. Higher intakes of polymeric flavan-3-ols (i.e., theaflavins, thearubigins, and proanthocyanidins) were correlated with lower concentrations of pro-inflammatory cytokines and biomarkers of oxidative stress. Intake levels of total flavonoids and flavan-3-ol monomers (i.e., catechins) were inversely associated with concentrations of the biomarkers of oxidative stress. Although tea is a major source of flavan-3-ols, tea consumption was not correlated with the composite inflammation score or any components of this score in this study (62).

Cocoa is another source of flavan-3-ols, in particular (-)-epicatechin and procyanidins, that may provide cardiovascular benefits (63). Indeed, a recent randomized, double-blind, placebo-controlled study in 100 healthy adults (ages, 35-60 years) suggested that short-term benefits of cocoa flavan-3-ol consumption on cardiovascular health, including improvements in lipoprotein profile (i.e., higher HDL-cholesterol and lower total and LDL-cholesterol) and blood pressure, could be extrapolated to predict a 20%-30% reduced 10-year risk of CVD and CVD-related mortality (64).

An increasing number of trials in which participants were fed with berries (65-67) or juices (68) rich in anthocyanins or with purified anthocyanins (69) also reported reduced levels of inflammatory markers and/or improved antioxidant status, decreased LDL-cholesterol, improved insulin sensitivity, and lowered blood pressure (reviewed in 70). In a randomized, double-blind, placebo-controlled study in 150 individuals with hypercholesterolemia, supplementation with a purified anthocyanin mixture (320 mg/day) for 24 weeks reduced circulating markers of inflammation, including C-reactive protein (CRP), interleukin-1β (IL-1β), and soluble vascular adhesion molecule-1 (sVCAM-1) (71). Supplementation of dyslipidemic patients for 12 or 24 weeks with a mixture of 17 anthocyanins improved cholesterol clearance via the HDL-mediated reverse cholesterol transport from extra-hepatic tissues back to the liver and lowered LDL-cholesterol compared to a placebo in two randomized controlled trials (72, 73). However, a 12-week, randomized, double-blind, placebo-controlled study in 52 healthy postmenopausal women found that daily consumption of 500 mg of elderberry anthocyanins (as cyanidin-3-glucoside) had no effect on inflammation markers, markers of vascular health, lipid profile, and glycemia; all of these measures were in normal range of concentrations at baseline (74). Whether exposure to high-dose anthocyanins could lower the risk of CVD in subjects with established CVD risk factors and/or help maintain cardiovascular health in apparently healthy individuals remains to be confirmed.

Endothelial dysfunction

The vascular endothelial cells that line the inner surface of all blood vessels synthesize an enzyme, endothelial nitric oxide synthase (eNOS), whose function is essential to normal vascular physiology. Specifically, eNOS produces nitric oxide (NO), a compound that regulates vascular tone and blood flow by promoting the relaxation (vasodilation) of all types of blood vessels, including arteries (75). NO also regulates vascular homeostasis and protects the integrity of the endothelium by inhibiting vascular inflammation, leukocyte adhesion, platelet adhesion and aggregation, and proliferation of vascular smooth muscle cells (76). In the presence of cardiovascular risk factors (e.g., hypertension, hypercholesterolemia, hyperglycemia), early alterations in the structure and function of the vascular endothelium are associated with the loss of normal NO-mediated endothelium-dependent vasodilation. Endothelial dysfunction results in widespread vasoconstriction and coagulation abnormalities and is considered to be an early step in the development of atherosclerosis. Measures of brachial flow-mediated dilation (FMD), a surrogate marker of endothelial function, have been found to be inversely associated with risk of future cardiovascular events (77).

Preclinical studies have demonstrated the benefits of berry fruits, extracts, or purified anthocyanins on vascular function. Anthocyanin supplementation to diabetic mice was found to improve diabetes-induced vascular dysfunction by promoting NO-mediated endothelium-dependent vasodilation through the upregulation of adipocyte-derived adiponectin (78). Supplementation with purified anthocyanins (320 mg/day for 12 weeks) also increased serum adiponectin concentrations and improved FMD in 58 individuals with type 2 diabetes (78). In a randomized trial of 150 participants with hypercholesterolemia, supplemental anthocyanins increased FMD values by 28.4% compared to 2.2% in the placebo group (79).

Several small-scale, intervention studies have also examined the effect of flavan-3-ol-rich food and beverages, including tea, red wine, purple grape juice, cocoa, and chocolate, on endothelium-dependent vasodilation. A meta-analysis of nine intervention studies in a total of 213 participants estimated that the acute ingestion of 2 to 3 cups of tea (500 mL) — containing about 248 mg of flavonoids in green tea and 415 mg in black tea — significantly increased brachial FMD (see also the article on Tea) (80). Another meta-analysis of 18 randomized controlled studies found that acute (2 h post-ingestion) and chronic (≤18 months) consumption of flavan-3-ol-rich cocoa beverages and chocolate bars significantly increased FMD in participants (81). A small 15-day, cross-over intervention study in hypertensive individuals with endothelial dysfunction found that 100 g/day of flavan-3-ol-rich dark chocolate, but not 90 g/day of flavan-3-ol-free white chocolate, could restore FMD values almost to normal levels (82). Also, using a similar protocol, the authors showed that dark chocolate intake blunted acute endothelial dysfunction-induced by a glucose load challenge in 12 healthy volunteers (83). Other benefits of dark chocolate consumption included reductions in arterial stiffness (measured through pulse wave analysis) and serum concentrations of markers of oxidative stress and vasoconstriction (8-isoprostaglandin F2α and endothelin-1). A randomized controlled trial in overweight and obese participants also reported that the daily consumption of a high-flavan-3-ol cocoa drink (902 mg/day of flavan-3-ols), but not that of a cocoa drink low in flavan-3-ols (38 mg/day), resulted in a sustained increase in FMD during the 12-week study (84). A more recent four-week, randomized, double-blind, cross-over, controlled study in healthy overweight or obese adults found that the consumption of 22 g/day of natural cocoa (in the form of dark chocolate bar and cocoa drink; 814 mg/day of flavan-3-ols) increased arterial diameter and blood flow and lowered peripheral arterial stiffness, but there was no change in FMD (85). Another recent clinical trial found improvements in endothelium-dependent vasodilation in response to acute consumption of one bar (40 g) of dark chocolate (containing 10.8 mg of (+)-catechins and 36 mg of (-)-epicatechins) and daily consumption of two bars (80 g) for up to four weeks in 20 individuals with chronic heart failure (86). Oral administration of pure flavan-3-ol (-)-epicatechin to healthy volunteers showed NO-dependent vasodilatory effects similar to those observed following flavan-3-ol-rich cocoa ingestion (87). Administration of (-)-epicatechin also improved acetylcholine-induced endothelial-dependent vasodilation of thoracic aorta rings from rats with salt-induced hypertension (88).

Endothelial nitric oxide production also inhibits the adhesion and aggregation of platelets, one of the first steps in atherosclerosis and blood clot formation (76). A number of clinical trials that examined the potential for high flavonoid intakes to decrease various measures of platelet function outside of the body (*ex vivo*) have reported mixed results. A recent systematic review of these intervention studies suggested that consumption of flavan-3-ol-rich cocoa and grape seed extract was generally found to improve platelet function by inhibiting platelet adhesion, activation, and aggregation (89). Interestingly, in a cross-over, controlled study, the acute consumption of a flavan-3-ol-rich cocoa beverage (897 mg of total (-)-EC and procyanidins) exhibited additive anti-platelet effects to aspirin (81 mg) in healthy volunteers (90). In contrast, the results of interventions using apigenin-rich soup, quercetin-rich supplements or onion soups, isoflavone-rich soy protein isolates, black tea, wines, berries, or grape juices have given inconsistent results (reviewed in 89).

Hypertension

A meta-analysis of 20 short-term, randomized controlled trials, including a total of 856 mainly healthy participants, found that consumption of flavan-3-ol-rich dark chocolate and cocoa products significantly reduced systolic blood pressure by 2.77 mm Hg and diastolic blood pressure by 2.20 mm Hg. However, heterogeneity across studies was high, and risk of bias was significant (91). A greater blood pressure-reducing effect was observed in a subanalysis of studies using flavan-3-ol-free rather than flavan-3-ol-low control groups (91). Another meta-analysis of 22 trials (highly heterogeneous) found reductions in diastolic blood pressure (-1.60 mm Hg) and mean arterial pressure (-1.64 mm Hg) with chocolate or cocoa intake but no change in systolic blood pressure (81). Additionally, green tea flavan-3-ols have been shown to lower blood pressure especially in (pre-) hypertensive subjects. A pooled analysis of 13 randomized controlled trials in 1,040 subjects found a 2.05 mm Hg reduction in systolic blood pressure and a 1.71 mm Hg reduction in diastolic blood pressure with green tea consumption for at least three weeks (92). The inhibition of angiotensin-converting enzyme (ACE), a key regulator of arterial blood pressure, may partly explain how flavan-3-ol-rich food and beverages might exert blood pressure-lowering effects (93).

Some intervention trials have also examined the effect of the flavonol quercetin on blood pressure in human subjects. In a randomized, double-blind, cross-over, placebo-controlled trial in 96 participants diagnosed with metabolic disorders, supplementation with 150 mg/day of quercetin aglycone significantly reduced systolic blood pressure by 2.6 mm Hg without affecting diastolic blood pressure and other cardiometabolic markers (94). Similar results were found with 730 mg/day of quercetin in hypertensive individuals (95) and with 500 mg/day of quercetin in women with type 2 diabetes mellitus (96). In a recent six-week, cross-over, randomized, double-blind, placebo-controlled trial, daily ingestion of 162 mg of quercetin decreased 24 h-ambulatory blood pressure — but not systolic blood pressure in the resting state — in hypertensive but not in pre-hypertensive participants (97). There was no change in biomarkers of lipid metabolism, inflammation, oxidative stress, or endothelial function, including total, HDL-, LDL-cholesterol, serum CRP, soluble adhesion molecules, plasma oxidized LDL, urinary 8-isoprostaglandin F2α, serum endothelin-1, serum ACE, and plasma endogenous NOS inhibitor.

Additional trials may help establish whether the blood pressure-lowering effect of some flavonoids could be translated into long-term benefits for cardiovascular health.

Type 2 diabetes mellitus

The association between flavonoid consumption and risk for type 2 diabetes mellitus has been examined in a recent European, multicenter, nested case-control study — the "EPIC-InterAct" project — that included 16,835 diabetes-free participants and 12,043 diabetics. In this study, participants in the highest quintile of total flavonoid intake (>608.1 mg/day) had a 10% lower risk of diabetes than those in the lowest quintile (<178.2 mg/day) (98). Specifically, the risk of diabetes was inversely correlated with the intake of flavan-3-ols (monomers and dimers only) and flavonols (98, 99). Recent meta-analyses of randomized controlled trials have examined the possible health effects of green tea flavan-3-ol monomers (catechins) on glucose metabolism and have provided conflicting results. A meta-analysis of seven trials in pre-diabetic and diabetic patients found no effect of green tea or green tea extracts on fasting plasma glucose, fasting serum insulin, or measures of glycemic control (glycated hemoglobin, HbA1c) and insulin sensitivity (HOMA-IR) (100). Conversely, another meta-analysis of 17 trials in pre-diabetic, diabetic, or overweight/obese subjects found that administration of green tea extracts for 4 to 16 weeks improved fasting plasma glucose and HbA1c level (101). The effect on fasting glucose was observed only with high doses of catechins (≥457 mg/day) and when the confounding effect of caffeine was removed. Finally, a third meta-analysis of 25 trials found that ingestion of green tea extracts for at least two weeks could lower fasting blood glucose in both the presence or absence of caffeine (102).

Dark chocolate is another good source of flavan-3-ols such that the effects of cocoa flavan-3-ols have been examined in individuals at-risk or with established type 2 diabetes. In a 15-day, cross-over, randomized controlled study, the daily consumption of 100 g of dark chocolate bars containing 110.9 mg of (-)-EC and 36.1 mg of (+)-C significantly improved measures of pancreatic β-cell function and insulin sensitivity, along with cardiometabolic markers in glucose-intolerant and hypertensive subjects (103). Daily supplementation with flavonoid-enriched chocolate containing 850 mg of flavan-3-ols and 100 mg of isoflavones for one year significantly improved insulin sensitivity and reduced a predicted risk of coronary heart disease (CHD) at 10 years in 93 postmenopausal women treated for type 2 diabetes (104).

The EPIC-InterAct study did not find any association between dietary anthocyanin intake and risk of diabetes (98, 99). Yet, a 10-fold increase in anthocyanin consumption was correlated with a 15% lower risk of diabetes in the pooled analysis of three large US prospective cohorts (120,003 participants) (105). Of note, this pooled analysis also reported a moderately higher risk of diabetes (+6%) in individuals in the highest versus lowest quintiles of flavone and flavanone intakes. Moreover, the consumption of berries, rich in anthocyanins, has been shown to trigger favorable glycemic responses in type 2 diabetics (reviewed in 70). In recent intervention studies, anthocyanins demonstrated beneficial effects on metabolic abnormalities in patients at-risk or diagnosed with diabetes. In an eight-week, randomized, double-blind, placebo-controlled trial in 38 healthy overweight and obese subjects, the consumption of 2 g/day of grape polyphenols rich in proanthocyanidins and anthocyanins prevented increases in oxidative stress and insulin resistance induced by a six-day, high-fructose challenge (106). Another six-week randomized trial in individuals with diabetes showed that daily supplementation with Cornelian cherry (*Cornus mas*) extracts containing 600 mg of anthocyanins significantly lowered serum levels of HbA1c and triglycerides and increased serum insulin concentrations (107). The administration of 320 mg/day of anthocyanins for 24 weeks also improved serum lipid and lipoprotein profile, decreased markers of oxidative stress and inflammation, elevated antioxidant capacity, and reduced insulin resistance compared to a placebo in patients with diabetes (108). Further, supplemental anthocyanins up-regulated adiponectin expression and improved nitric oxide-mediated endothelium-dependent vasodilation within 12 weeks of treatment (see also Cardiovascular disease) (78).

These promising findings warrant additional randomized controlled trials to confirm preventive and/or therapeutic benefits of (cocoa) flavan-3-ols and anthocyanins in type 2 diabetes.

Cancer

Although various flavonoids have been found to inhibit the development of chemically-induced cancers in animal models of lung (109), oral (110), esophageal (111), gastric (112), colon (113), skin (114), prostate (115, 116), and mammary cancer (117), observational studies do not provide convincing evidence that high intakes of dietary flavonoids are associated with substantial reductions in human cancer risk (reviewed in 118). A meta-analysis of 13 case-control and 10 prospective cohort studies found little-to-no evidence to support a preventive role of dietary flavonoid intake in gastric and colorectal cancer (119). In addition, a recently published analysis of two large prospective studies (the Health Professionals Follow-up Study [HPFS] and the Nurses' Health Study [NHS]) — using the most up-to-date flavonoid food composition databases — found no association between the risk of colorectal cancer and intakes of each subclass of flavonoids or flavonoid-rich foods (tea, blueberries, oranges) (120). A meta-analysis of 19 case-control studies and 15 cohort studies found that total flavonoid intake and intakes of specific flavonoid subclasses (i.e., flavonols, flavones, flavanones) were inversely correlated with the risk of smoking-sensitive cancers of the aerodigestive tract (mouth, pharynx, larynx, esophagus, and stomach) in smokers but not in nonsmokers (121). The risk of lung cancer was not significantly associated with high flavonoid intakes (121), although an earlier meta-analysis of eight prospective studies (with substantial heterogeneity across them) suggested a protective role of flavonoids against lung cancer in smokers only (122). Further, a prospective analysis of over 45,000 postmenopausal women from the Multiethnic Cohort Study found a reduced risk of endometrial cancer with the highest intakes of total isoflavones, daidzein, and genistein (123). Additionally, limited evidence from observational studies suggests no relationship between total flavonoid intake and ovarian cancer (124-127). To date, there is little evidence that flavonoid-rich diets might protect against various cancers, but larger prospective cohort studies are needed to address the association.

Hormone-dependent cancers

Because isoflavones are phytoestrogens, it is thought that they may interfere with the synthesis and activity of endogenous hormones, eventually influencing hormone-dependent signaling pathways and protecting against breast and prostate cancers (128). A meta-analysis of 14 observational studies that examined breast cancer incidence in 369,934 women found an overall 11% reduced risk of breast cancer with the highest versus lowest intake of soy isoflavones (129). Subgroup analyses revealed a 24% lower risk of cancer in Asian but not in European or US women, and the risk was 22% lower in postmenopausal but not lower in premenopausal women. In addition to the ethnicity and menopausal status, polymorphisms for hormone receptors (130) and phase I biotransformation enzymes (131) have been found to modify the association between isoflavone intake and breast cancer. Another recent meta-analysis of 12 observational studies (six prospective cohort studies, one nested case-control study, and five case-control studies) investigated the chemopreventive effects of flavonoids (except isoflavones) (132). The results suggested that intakes of flavonols and flavones may also be inversely associated with the risk of breast cancer. Further, a pooled analysis of four case-control studies that stratified by menopausal status showed inverse associations between breast cancer and intakes of flavonols, flavones, or flavan-3-ols in postmenopausal women only. Finally, a meta-analysis of four prospective cohort studies found an overall 16% reduced risk of breast cancer recurrence in women with high versus low isoflavone intakes (129).

A meta-analysis of 13 observational studies also suggested an inverse relationship between prostate cancer risk and consumption of soy products, especially tofu (133). Yet, further analyses supported a protective role of soy food based only on case-control studies, which have inherent flaws such that associations may often be overestimated or underestimated. In a recent 12-month, multicenter, randomized, double-blind, placebo-controlled phase II clinical trial in 158 Japanese men (aged ≥50 years) with elevated risk of prostate cancer, oral isoflavone (60 mg/day) resulted in a significant decrease in prostate cancer incidence in participants aged 65 years and older (134). In this study, no changes were reported in sex hormone concentrations in blood, suggesting that isoflavones may reduce prostate cancer incidence without interfering with hormone-dependent pathways.

Additional investigations will be necessary to determine whether supplementation with specific flavonoids could benefit cancer prevention or treatment.

For more information on flavonoid-rich foods and cancer, see articles on Fruit and Vegetables, Legumes, and Tea.

Cognitive function

Inflammation, oxidative stress, and transition metal accumulation appear to play a role in the pathology of several neurodegenerative diseases, including Parkinson's disease and Alzheimer's disease (135). Therefore, the various properties of flavonoids, including their role in protecting vascular health, could have beneficial effects on the brain, possibly in the protection against cerebrovascular disorders, cognitive impairments, and subsequent stroke and dementias. Dietary flavonoids and/or their metabolites have been shown to cross the blood-brain barrier (54) and exert preventive effects towards cognitive impairments in animal models of normal and pathological aging (53).

The cross-sectional data analysis of 2,031 participants (ages, 70-74 years) from the Hordaland Health Study in Norway indicated that, when compared to non-consumers, consumers of flavonoid-rich chocolate, tea, and wine had better global cognitive function, assessed by a battery of six cognitive tests (136). The risk of poor performance in all tests was estimated to be 60 to 74% lower in consumers of all three flavonoid-rich foods compared to non-consumers. An early prospective cohort study in 1,367 older French men and women (aged ≥65 years; free from dementia at baseline) found that those with the lowest flavonoid intakes (<11.5 mg/day) had a 50% higher risk of developing dementia over the next five years than those with higher intakes (137). In addition, those with higher dietary flavonoid intakes at baseline experienced significantly less age-related cognitive decline over a 10-year period than those with the lowest flavonoid intakes (138).

The effect of cocoa flavan-3-ols have been investigated in an eight-week, randomized, double-blind trial — the Cognitive, Cocoa, and Aging (CoCoA) study — in 90 individuals (ages, 64-82 years) with mild cognitive impairments (MCI); participants were given dairy-based cocoa drinks with either high (993 mg/day) or low (48 mg/day) levels of flavan-3-ols (139). The daily consumption of the cocoa drink high in flavan-3-ols improved some, but not all, measures of cognitive process speed and flexibility and verbal fluency compared to baseline test scores and scores following low flavan-3-ol drink consumption. A composite test score reflecting overall cognitive performance was found to be significantly greater in those given cocoa drinks high rather than low in flavan-3-ols. The study also reported reductions in cardiovascular risk markers (i.e., systolic and diastolic blood pressure, total and LDL-cholesterol, insulin resistance), and these changes were proposed to partly contribute to ameliorate cognitive performance in those who consumed the flavan-3-ol-rich cocoa drink (139). The data could be replicated in cognitively healthy older people (ages, 61-85 years), suggesting that cocoa flavan-3-ols might enhance some aspects of cognitive function during healthy aging (140). Interestingly, a two-week, randomized, double-blind, controlled study has reported an increase in blood flow velocity in the middle cerebral artery of 21 healthy subjects (mean age, 72 years) following the daily intake of a flavan-3-ol-rich cocoa drink (900 mg/day of flavan-3-ols) (141). Because cerebral blood flow is correlated with cognitive function in humans, these preliminary data suggest that cocoa flavan-3-ol consumption could exert a protective effect against dementia (54).

Yet, in other randomized controlled trials (142-144), the lack of an effect of cocoa flavan-3-ols on blood pressure, cerebral blood flow, mental fatigue, and cognitive performance in healthy young and old adults suggested that benefits may only be seen in very demanding cognitive exercises (145).

Some randomized controlled studies also reported improvements in measures of cognitive function in healthy and cognitively impaired subjects with other flavonoid subclasses, including anthocyanins (146), flavanones (147, 148), and isoflavones (149, 150). Although some flavonoids and flavonoid-rich foods may enhance cognitive function in the aging brain, it is not yet clear whether their consumption could lower the risk of cognitive impairments and dementia in humans.

For more detailed information on flavan-3-ol-rich tea and cognitive function, see the article on Tea.

Sources

Food sources

Recent data analyses of the National Health and Nutrition Examination Survey (NHANES) estimated flavonoid intakes in US adults (aged ≥19 years) average between 200 and 250 mg/day, with 80% being flavan-3-ols, 8% for flavonols, 6% for flavanones, 5% for anthocyanidins, and ≤1% for isoflavones and flavones (151, 152). The main dietary sources of flavonoids include tea, citrus fruit, citrus fruit juices, berries, red wine, apples, and legumes. Individual flavonoid intakes may vary considerably depending on whether tea, red wine, soy products, or fruit and vegetables are commonly consumed (reviewed in 2). Information on the flavonoid content of some flavonoid-rich foods is presented in **Tables 2-8**. These values should be considered approximate since a number of factors may affect the flavonoid content of foods, including agricultural practices, environmental conditions, ripening, storage, and food processing. For additional information about the flavonoid content of food, the USDA provides databases for the content of selected foods in flavonoids (60) and proanthocyanidins (58). For more information on the isoflavone content of soy foods, see the article on Soy Isoflavones or the USDA database for the isoflavone content of selected foods (59).

Supplements

Anthocyanins

Bilberry, elderberry, black currant, blueberry, red grape, and mixed berry extracts that are rich in anthocyanins are available as dietary supplements without a prescription in the US. The anthocyanin content of these products may vary considerably. Standardized extracts that list the amount of anthocyanins per dose are available.

Flavan-3-ols

Numerous tea extracts are available in the US as dietary supplements and may be labeled as tea catechins or tea polyphenols. Green tea extracts are the most commonly marketed, but black and oolong tea extracts are also available. Green tea extracts generally have higher levels of catechins (flavan-3-ol monomers), while black tea extracts are richer in theaflavins and thearubigins (tea flavan-3-ol dimers and polymers, respectively). Oolong tea extracts fall somewhere in between green and black tea extracts with respect to their flavan-3-ol content. Some tea extracts contain caffeine, while others are decaffeinated. Flavan-3-ol and caffeine content vary considerably among different products, so it is important to check the label or consult the manufacturer to determine the amounts of flavan-3-ols and caffeine that would be consumed daily with each supplement (for more information on tea flavan-3-ols, see the article on Tea).

Flavanones

Citrus bioflavonoid supplements may contain glycosides of hesperetin (hesperidin), naringenin (naringin), and eriodictyol (eriocitrin). Hesperidin is also available in hesperidin-complex supplements, with daily doses from 500 mg to 2 g (153).

Flavones

The peels and tissues of citrus fruit (e.g., oranges, tangerines, and clementines) are rich in polymethoxylated flavones: tangeretin, nobiletin, and sinensetin (2). Although dietary intakes of these naturally occurring flavones are generally low, they are often present in citrus bioflavonoid complex supplements. Several dietary supplements may also contain various amounts of baicalein (aglycone) and/or baicalin (glycoside). Some tea preparations may also include baicalein-7-glucuronide (153).

Flavonols

The flavonol aglycone, quercetin, and its glycoside rutin are available as dietary supplements without a prescription in the US. Other names for rutin include rutoside, quercetin-3-rutinoside, and sophorin (153). Citrus bioflavonoid supplements may also contain quercetin or rutin.

Isoflavones

A 50-mg soy isoflavone supplement usually includes glycosides of the isoflavones: genistein (genistin; 25 mg), daidzein (daidzin; 19 mg), and glycitein (glycitin; about 6 mg). Smaller amounts of daidzein, genistein, and formononetin are also found in biochanin A-containing supplements (derived from red clover) (153).

Safety

Adverse effects

No adverse effects have been associated with high dietary intakes of flavonoids from plant-based food. This lack of adverse effects may be explained by the relatively low bioavailability and rapid metabolism and elimination of most flavonoids.

Quercetin

Oral supplementation with quercetin glycosides at doses ranging between 3 mg/day-1,000 mg/day for up to three months has not resulted in significant adverse effects in clinical studies (reviewed in 154). A randomized, placebo-controlled study in 30 patients with chronic prostatitis reported one case of headache and another of tingling of the extremities associated with supplemental quercetin (1,000 mg/day for one month); both issues resolved after the study ended (155). In a phase I clinical trial in cancer patients unresponsive to standard treatments, administration of quercetin via intravenous infusion resulted in symptoms of nausea, vomiting, sweating, flushing, and dyspnea (difficulty breathing) at doses ≥10.5 mg/kg body weight (~756 mg of quercetin for a 70 kg individual) (156). Higher doses up to 51.3 mg/kg body weight (~3,591 mg of quercetin) were associated with renal (kidney) toxicity, yet without evidence of nephritis, infection, or obstructive uropathy (reviewed in 154).

Cocoa flavan-3-ols

In a recent randomized, double-blind, controlled study in healthy adults, the daily intake of 2 g of cocoa flavan-3-ols for 12 weeks was found to be well tolerated with no adverse side effects (157).

Tea extracts

In clinical trials employing caffeinated green tea extracts, cancer patients who took 6 g/day in three to six divided doses reported mild-to-moderate gastrointestinal side effects, including nausea, vomiting, abdominal pain, and diarrhea (158, 159). Central nervous system symptoms, including agitation, restlessness, insomnia, tremors, dizziness, and confusion, have also been reported. In one case, confusion was severe enough to require hospitalization (158). In a systematic review published in 2008, the US Pharmacopeia (USP) Dietary Supplement Information Expert Committee identified 34 adverse event reports implicating the use of green tea extract products (containing 25%-97% of polyphenols) as the likely cause of liver damage (hepatotoxicity) in humans (160). In a four-week clinical trial that assessed the safety of decaffeinated green tea extracts (800 mg/day of EGCG) in healthy individuals, a few of the participants reported mild nausea, stomach upset, dizziness, or muscle pain (161). In the Minnesota Green Tea Trial (MGTT), 1,075 postmenopausal women were randomized to receive green tea extracts (1,315±116 mg/day of catechins; the equivalent of four 8-ounce mugs of brewed decaffeinated green tea) or a placebo for one year. The total number of adverse events and the number of serious adverse events were not different between the treatment and placebo groups (162). However, the use of green tea extracts was directly associated with abnormally high liver enzyme levels in 7 out of the 12 women who experienced serious adverse events. Also, the incidence of nausea was twice as high in the green tea arm as in the placebo group (162).

Pregnancy and lactation

The safety of flavonoid supplements in pregnancy and lactation has not been established (153).

Drug interactions

Inhibition of ABC drug transporters

ATP-binding cassette (ABC) drug transporters, including P-glycoprotein, multidrug resistance protein (MRP), and breast cancer-resistant protein (BCRP), function as ATP-dependent efflux pumps that actively regulate the excretion of a number of drugs limiting their systemic bioavailability (8). ABC transporters are found throughout the body, yet they are especially important in organs with a barrier function like the intestines, the blood-brain barrier, blood-testis barrier, and the placenta, as well as in liver and kidneys (163). There is some evidence that the consumption of grapefruit juice inhibits the activity of P-glycoprotein (164). Genistein, biochanin A, quercetin, naringenin, hesperetin, green tea flavan-3-ol (-)-CG, (-)-ECG, and (-)-EGCG, and others have been found to inhibit the efflux activity of P-glycoprotein in cultured cells and in animal models (163). Thus, very high or supplemental intakes of these flavonoids could potentially increase the toxicity of drugs that are substrates of P-glycoprotein, e.g., digoxin, antihypertensive agents, antiarrhythmic agents, chemotherapeutic (anticancer) agents, antifungal agents, HIV protease inhibitors, immunosuppressive agents, H_2 receptor antagonists, some antibiotics, and others (reviewed in 165).

Many anthocyanins and anthocyanidins, as well as some flavones (apigenin, chrysin), isoflavones (biochanin A, genistein), flavonols (kaempferol), and flavanones (naringenin), have been identified as inhibitors of BRCP-mediated transport, theoretically affecting drugs like anticancer agents (mitoxantrone, topotecan, thyrosine kinase inhibitors), antibiotics (fluoroquinolones), β-blockers (prazosin), and antiarthritics (sulfasalazine). Finally, flavonols (quercetin, kaempferol, myricetin), flavanones (naringenin), flavones (apigenin, robinetin), and isoflavones (genistein) have been reported to inhibit MRP, potentially affecting MRP-mediated transport of many anticancer drugs, e.g., vincristin, etoposide, cisplatin, irinotecan, methotrexate, camptothecin, anthracyclines, vinca alkaloids (reviewed in 163).

Anticoagulant and antiplatelet drugs

High intakes of flavonoids from purple grape juice (500 mL/day) and dark chocolate (235 mg/day of flavan-3-ols) have been found to inhibit platelet aggregation in *ex vivo* assays (166-169). Theoretically, high intakes of flavonoids (e.g., from supplements) could increase the risk of bleeding when taken with anticoagulant drugs, such as warfarin (Coumadin), heparin, dalteparin (Fragmin), enoxaparin (Lovenox), and antiplatelet drugs, such as clopidogrel (Plavix), dipyridamole (Persantine), non-steroidal anti-inflammatory drugs (NSAIDs: diclofenac, ibuprofen, naproxen), aspirin, and others (170).

Inhibition of CYP 3A4 by flavonoid-rich grapefruit

Cytochrome P450 (CYP) enzymes are phase I biotransformation enzymes involved in the metabolism of a broad range of compounds, from endogenous molecules to therapeutic agents. The most abundant CYP isoform in the liver and intestines is cytochrome P450 3A4 (CYP3A4); the CYP3A family catalyzes the metabolism of about one-half of all marketed drugs in the US and Canada (171). One grapefruit or as little as 200 mL (7 fluid ounces) of grapefruit juice have been found to irreversibly inhibit intestinal CYP3A4 (164). The most potent inhibitors of CYP3A4 in grapefruit are thought to be furanocoumarins, particularly dihydroxybergamottin, rather than flavonoids. All forms of the fruit — freshly squeezed juice, frozen concentrate, or whole fruit — can potentially affect the activity of CYP3A4. Some varieties of other citrus fruit (Seville oranges, limes, and pomelos) that contain furanocoumarins can also interfere with CYP3A4 activity.

Specifically, the inhibition of intestinal CYP3A4 by grapefruit consumption is known or predicted to increase the bioavailability and the risk of toxicity of more than 85 drugs. Because drugs with very low bioavailability are more likely to be toxic when CYP3A4 activity is inhibited, they are associated with a higher risk of overdose with grapefruit compared to drugs with high bioavailability. Some of the drugs with low bioavailability include, but are not limited to, anticancer drugs (everolimus); anti-infective agents halofantrine, maraviroc); statins (atorvastatin, lovastatin, and simvastatin); cardioactive drugs (amiodarone, clopidogrel, dronedarone, eplenorone, ticagrelor); HIV protease inhibitors (saquinavir), immunosuppressants (cyclosporine, sirolimus, tacrolimus, everolimus); antihistamines (terfenadine); gastrointestinal agents (domperidone); central nervous system agents (buspirone, dextromethorphan, oral ketamine, lurasidone, quetiapine, selective serotonin reuptake inhibitors [sertraline]); and urinary tract agents (darifenacin) (reviewed in 171). Because of the potential for adverse drug interactions, some clinicians recommend that people taking medications with low bioavailability (i.e., undergoing extensive metabolism by CYP3A4) avoid consuming grapefruit and grapefruit juice altogether during the treatment period (171).

Nutrient interactions

Iron

Flavonoids can bind nonheme iron, inhibiting its intestinal absorption (172, 173). Nonheme iron is the principal form of iron in plant foods, dairy products, and iron supplements. The consumption of one cup of tea or cocoa with a meal has been found to decrease the absorption of nonheme iron in that meal by about 70% (174, 175). Flavonoids can also inhibit intestinal heme iron absorption (176). Interestingly, ascorbic acid greatly enhances the absorption of iron (see the article on Iron) and is able to counteract the inhibitory effect of flavonoids on nonheme and heme iron absorption (173, 176, 177). To maximize iron absorption from a meal or iron supplements, flavonoid-rich food and beverages and flavonoid supplements should not be consumed at the same time.

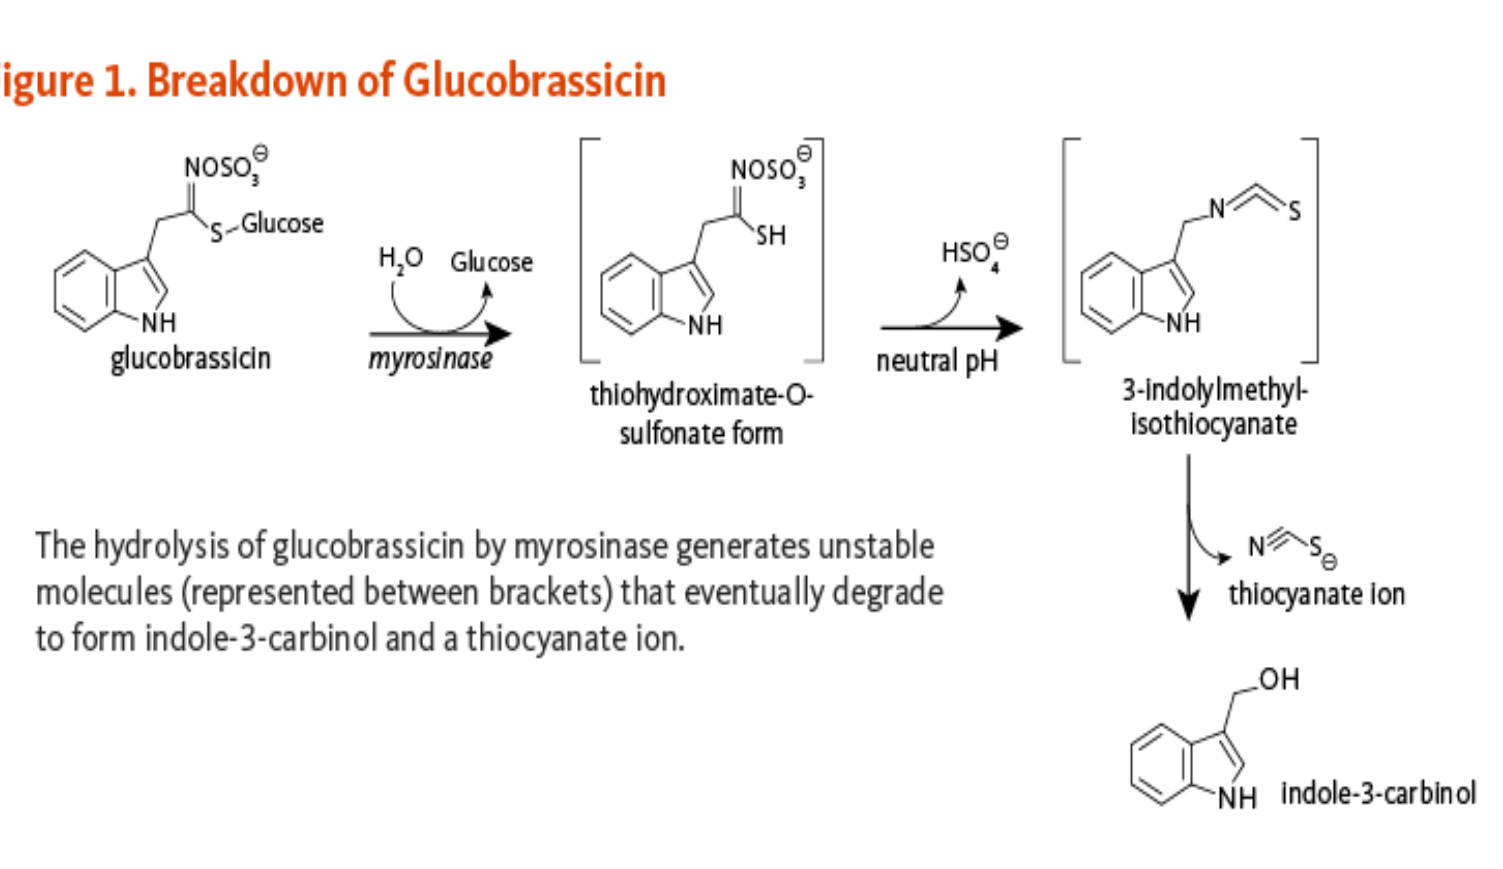
Summary

- Indole-3-carbinol (I3C) is derived from the breakdown of glucobrassicin, a compound found in cruciferous vegetables. *(More information)*
- In the stomach, I3C molecules undergo acid-catalyzed condensation that generates a number of biologically active I3C oligomers, such as 3,3'-diindolylmethane (DIM) and 5,11-dihydroindolo-[3,2-*b*]carbazole (ICZ). *(More information)*
- I3C and DIM have been found to modulate the expression and activity of biotransformation enzymes that are involved in the metabolism and elimination of many biologically active compounds, including steroid hormones, drugs, carcinogens, and toxins. *(More information)*
- Preclinical studies suggested that anti-estrogenic activities of I3C and DIM might help reduce the risk of hormone-dependent cancers. Although supplementation with I3C and DIM could alter urinary estrogen metabolite profiles in women, the effects of I3C and DIM on breast cancer risk are not known. *(More information)*
- Preclinical studies showed that I3C and I3C oligomers could affect multiple signaling pathways that are dysregulated in cancer cells, such as those controlling cell proliferation, apoptosis, migration, invasion, and angiogenesis. *(More information)*
- Limited evidence from preliminary trials suggested that I3C supplementation may help treat conditions related to human papilloma virus (HPV) infection, such as cervical/vulvar intraepithelial neoplasias and recurrent respiratory papillomatosis. However, randomized controlled trials are needed to determine whether I3C supplementation is beneficial. *(More information)*
- The timing of I3C exposure in animal models of chemically-induced cancers seems to determine whether I3C inhibits or promotes the development of tumors. Some experts have cautioned against the widespread use of I3C and DIM supplements for cancer prevention in humans until their potential risks and benefits are better understood. *(More information)*

Introduction

Some observational studies have reported significant associations between high intakes of cruciferous vegetables and lower risk of several types of cancer (1). Cruciferous vegetables differ from other classes of vegetables in that they are rich sources of sulfur-containing compounds known as glucosinolates (for detailed information, see the article on Cruciferous Vegetables) (2). The potential health benefits of consuming cruciferous vegetables are attributed to compounds derived from the enzymatic hydrolysis (breakdown) of glucosinolates. Among these compounds is indole-3-carbinol (I3C), a compound derived from the degradation of an indole glucosinolate commonly known as glucobrassicin (**Figure 1**).

Figure 1. Breakdown of Glucobrassicin



The hydrolysis of glucobrassicin by myrosinase generates unstable molecules (represented between brackets) that eventually degrade to form indole-3-carbinol and a thiocyanate ion.

[Figure 1 - Click to Enlarge]

Metabolism and Bioavailability

A number of commonly consumed cruciferous vegetables, including broccoli, Brussels sprouts, and cabbage, are good sources of glucobrassicin — the glucosinolate precursor of I3C (see Food sources).

Myrosinase (β-thioglucosidase), an enzyme that catalyzes the hydrolysis of glucosinolates, is physically separated from glucosinolates in intact plant cells (3). When raw cruciferous vegetables are chopped or chewed, plant cells are damaged such that glucobrassicin is exposed to myrosinase. The hydrolysis of glucobrassicin initially produces a glucose molecule and the unstable aglycone, thiohydroximate-O-sulfonate. The spontaneous release of a sulfate ion results in the formation of another unstable intermediate form, 3-indolylmethylisothiocyanate (4). This compound easily splits into thiocyanate ion and I3C (**Figure 1**). In the acidic environment of the stomach, I3C molecules can combine with each other to form a complex mixture of polycyclic aromatic compounds, known collectively as acid condensation products (**Figure 2**) (5). Some of the most prominent acid condensation products include 3,3'-diindolylmethane (DIM), 5,11-dihydroindolo-[3,2-*b*]carbazole (ICZ), and a cyclic triindole (CT) (**Figure 2**). The biological activities of individual acid condensation products may differ from those of I3C (see Biological Activities).

When cruciferous vegetables are cooked, plant myrosinase is inactivated thus the hydrolysis of glucosinolates is prevented. Intact glucosinolates then transit to the colon and are metabolized by human intestinal bacteria. The generation of I3C from glucobrassicin may still occur to a lesser degree in the large intestine, due to the myrosinase activity of colonic bacteria (4). Thus, when cruciferous vegetables are cooked, I3C can still form in the colon, but I3C-derived acid condensation products are less likely to form in the more alkaline environment of the intestine.

No I3C could be detected in plasma following oral administration of single doses of I3C, ranging from 200 to 1,200 mg, to healthy women at high risk for breast cancer (6). However, DIM was detected and peaked in plasma around two hours after I3C ingestion, at concentrations from <100 nanograms per milliliter (ng/mL) with oral doses of 400 to 600 mg of I3C up to 500 ng/mL-600 ng/mL with oral doses of 1,000 to 1,200 mg of I3C. All DIM disappeared from the blood within 24 hours (6).

Formulation strategies, such as the encapsulation of I3C and DIM into nanoparticles or liposomes (7-9), are being developed with the aim of increasing the bioavailability and evaluating the safety and efficacy of these compounds in humans.

Biological Activities

Effects on biotransformation enzymes

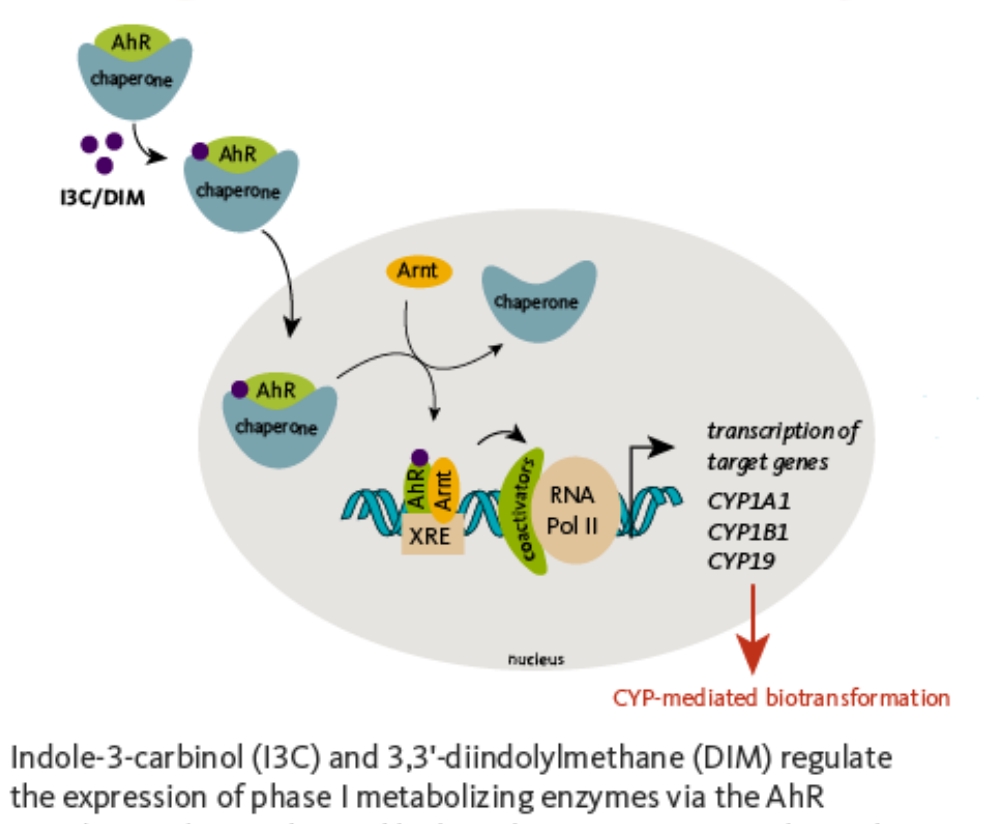
Biotransformation enzymes play major roles in the metabolism and elimination of many biologically active compounds, including physiologic regulators (e.g., estrogens), drugs, and environmental chemicals (xenobiotics; e.g., carcinogens, toxins). In general, phase I metabolizing enzymes, including the cytochrome P450 (CYP) family, catalyze reactions that increase the reactivity of hydrophobic (fat-soluble) compounds, which prepares them for reactions catalyzed by phase II detoxifying enzymes. Reactions catalyzed by phase II enzymes usually increase water solubility and promote the elimination of these compounds (10).

Aryl hydrocarbon receptor (AhR) pathway

I3C and some I3C condensation products can bind to a protein in the cytoplasm of cells called the aryl hydrocarbon receptor (AhR) (**Figure 3**) (11-13). In fact, ICZ is one of the most potent ligands for the AhR known with an affinity approaching that of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). I3C acid condensation products, as well as indoles and their acid condensation products formed from tryptophan metabolism, appear to be important endogenous ligands for the AhR (13). Binding allows AhR to enter the nucleus where it forms a complex with the AhR nuclear translocator (Arnt) protein. This AhR/Arnt complex binds to specific DNA sequences, known as xenobiotic response elements (XRE), in the regulatory regions (promoters) of target genes, especially those involved in xenobiotic metabolism (14). The promoters of genes coding for a number of CYP enzymes and several phase II enzymes contain XREs. Microarray gene expression profiling of I3C- or DIM-treated human prostate cancer cells showed that both compounds upregulated the phase I enzyme, CYP1A1, and the phase II enzymes, glutathione S-transferase theta-1 (GST q1) and aldo-keto reductase (15). Another study in human prostate cancer cells demonstrated that the removal of AhR abolished I3C- or DIM-induced CYP1A1 mRNA expression (16). The expression of CYP1A1 and CYP1A2 was also upregulated in human primary liver cells challenged with DIM (17). Further, I3C and DIM have been found to interfere with CYP activities involved in estrogen metabolism (see Anti-estrogenic activities).

Increasing the activity of biotransformation enzymes is generally considered a beneficial effect because the elimination of potential carcinogens or toxins is enhanced. However, there is a potential for adverse effects because some procarcinogens require biotransformation by phase I enzymes to become active carcinogens (18).

Figure 3. I3C and DIM Regulate Phase I Biotransformation Enzymes via AhR Signaling



Indole-3-carbinol (I3C) and 3,3'-diindolylmethane (DIM) regulate the expression of phase I metabolizing enzymes via the AhR signaling pathway. *AhR, aryl hydrocarbon receptor; Arnt, AhR nuclear translocator; CYP, cytochrome P450; RNA Pol II, RNA polymerase II; XRE, xenobiotic response element.*

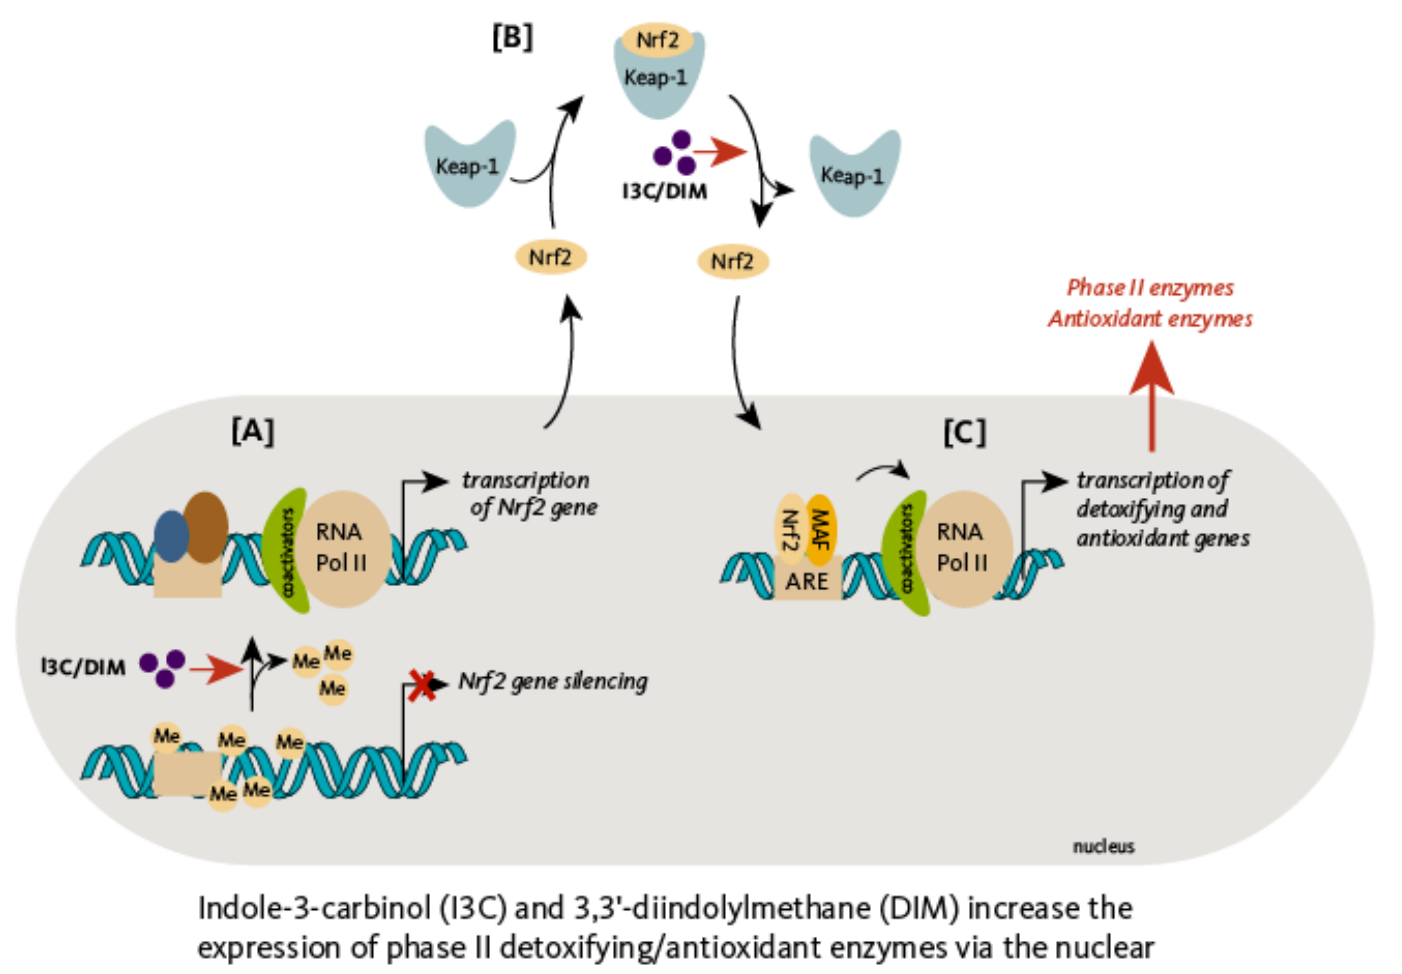
[Figure 3 - Click to Enlarge]

Nuclear factor E2-related factor 2-dependent pathway

I3C and DIM have been shown to induce the expression of phase II detoxifying and antioxidant enzymes via the activation of the nuclear factor E2-related factor 2 (Nrf2)-dependent pathway.

Briefly, Nrf2 is a transcription factor that is bound to the protein Kelch-like ECH-associated protein 1 (Keap1) in the cytosol (**Figure 4**). Keap1 responds to oxidative stress signals or chemical inducers by freeing Nrf2. Upon release, Nrf2 translocates to the nucleus and binds to the antioxidant response element (ARE) located in the promoters of genes coding for antioxidant/detoxifying enzymes and scavengers. Nrf2/ARE-dependent genes code for numerous mediators of the antioxidant response, including glutathione S-transferases (GSTs), thioredoxin, NAD(P)H quinone oxidoreductase 1 (NQO-1), and heme oxygenase 1 (HO-1) (19). DIM induced Nrf2/ARE-dependent upregulation of HO-1, and I3C stimulated NQO-1 and GST (μ2 isoform) expression in liver cancer cells (20). In addition, the transcription of *Nrf2* coding gene, which was abnormally repressed through promoter DNA hypermethylation, was enhanced in mouse prostate cancer cells treated with DIM. DIM subsequently restored the expression of the Nrf2-target genes, *NQO1* and *GSTμ1* (21). DIM also reversed *Nrf2* gene silencing in transgenic mouse prostate cancer tissues, including Nrf2 expression, and subsequently, NQO1 expression (**Figure 4**). This was accompanied by the suppression of proliferation and the induction of apoptosis in prostate cancer tissues (21). Similar observations have been reported with I3C (22).

Figure 4. I3C and DIM Regulate Phase II Biotransformation Enzymes via Nrf2 Signaling



Indole-3-carbinol (I3C) and 3,3'-diindolylmethane (DIM) increase the expression of phase II detoxifying/antioxidant enzymes via the nuclear factor E2-related factor 2 (Nrf2) signaling pathway. [A] I3C and DIM restore the transcription of Nrf2 gene by reversing promoter methylation, [B] I3C and DIM induce the nuclear translocation of Nrf2, and [C] I3C and DIM increase the expression of Nrf2 target genes coding for phase II enzymes and antioxidant enzymes. *ARE, antioxidant response element; Keap-1, Kelch-like ECH-associated protein 1; MAF, Nrf2 transcriptional cofactor; Me, methyl group; RNA Pol II, RNA polymerase II.*

[Figure 4 - Click to Enlarge]

Anti-estrogenic activities

Endogenous estrogens are steroid hormones synthesized by humans and other mammals.

Inhibition of estrogen synthesis

In breast tissue, CYP19 (aromatase) catalyzes the final steps in the conversion of androgens (testosterone or androstenedione) to estrogens (17β-estradiol or estrone, respectively). Both I3C and DIM have been found to downregulate the expression of CYP19 in non-tumorigenic and tumorigenic estrogen-responsive (ER$^+$) breast cells, whereas CYP19 expression was increased in I3C/DIM-treated tumorigenic estrogen-independent (ER$^-$) breast cells (23).

Inhibition of estrogen metabolic activation

Prolonged exposure to estrogens is thought to play a role in cancer development through CYP-mediated generation of estrogen reactive metabolites that can damage DNA (24, 25).

Phase I metabolizing enzymes, CYP1A1, CYP1A2, and CYP1B1, have been involved in the oxidative metabolism of estrogens. 17β-estradiol can be converted to 2-hydroxyestradiol (2HE$_2$) and 4-hydroxyestradiol (4HE$_2$) by CYP1A1/2 and CYP1B1, respectively. 2HE$_2$ and 4HE$_2$ are further metabolized to 2- and 4-metoxymetabolites by the phase II enzyme, catechol-*O*-methyltransferase (COMT) (25). 2HE$_2$ is a noncarcinogenic agent with weaker estrogenic potential than 17β-estradiol, while 4-HE$_2$ can be converted to free radicals that can form DNA adducts and promote carcinogenesis (26, 27). In different breast cancer cell lines, I3C and DIM have been shown to upregulate the expression of CYP1A1, CYP1A2, and CYP1B1 at the transcript (mRNA) level but not at the protein level (28).

Additionally, the endogenous estrogens 17β-estradiol and estrone can be irreversibly metabolized to 16a-hydroxyestrone (16HE$_1$) (29). In contrast to 2-hydroxyestrone (2HE$_1$), 16HE$_1$ is highly estrogenic and has been found to stimulate the proliferation of several estrogen-sensitive cancer cell lines (30, 31). It has been hypothesized that shifting the metabolism of 17β-estradiol toward 2HE$_1$, and away from 16HE$_1$, could decrease the risk of estrogen-sensitive cancers, such as breast cancer (32). In controlled clinical trials, oral supplementation with I3C or DIM has consistently increased urinary 2HE$_1$ concentrations or urinary 2HE$_1$:16HE$_1$ ratios in women (33-39). However, large case-control and prospective cohort studies have failed to find significant associations between urinary 2HE$_1$:16HE$_1$ ratios and risk of breast and endometrial cancer (40-43).

Inhibition of estrogen signaling

Endogenous estrogens, including 17β-estradiol, exert their estrogenic effects by binding to specific nuclear receptors called estrogen receptors (ERs). Within the nucleus, estrogen-activated ERs can bind to specific DNA sequences, known as estrogen response elements (EREs), in the promoters of estrogen-responsive genes. ERE-bound estrogen-ER complexes act as transcription factors by recruiting coactivator proteins and chromatin remodeling factors to promoters, thereby triggering the transcription of target genes (44). There are two major ER subtypes, ERα and ERβ, coded by two separate genes *ESR1* and *ESR2*, respectively. ERα is the main driver of the proliferative effect of estrogens, while the expression of ERβ has been inversely associated with mammary gland tumorigenesis (45). Elevated ERα levels promote cellular proliferation in the breast and uterus, possibly increasing the risk of developing estrogen-sensitive cancers (46).

Inhibition of estrogen-dependent cell proliferation

In estrogen-sensitive human breast cancer cells challenged with 17β-estradiol, I3C has been found to inhibit the transcription of estrogen-responsive genes without binding to either ERβ or ERα (47, 48). In fact, the binding of I3C to AhR was shown to trigger the proteasome-dependent degradation of ERα (49). I3C-induced loss of ERα resulted in the downregulation of ERα-responsive gene products like the transcription factor GATA3. Since GATA3 regulates the transcription of the ERα coding gene *ESR1*, I3C prevented the synthesis of new ERα transcripts and proteins, eventually abolishing the ERα signaling pathway. The disruption of the GATA3/ERα cross-regulatory loop by I3C ultimately halted ERα-dependent cell proliferation (49). Acid condensation products of I3C that bind and activate AhR may also inhibit the transcription of estrogen-responsive genes by competing for co-activators or increasing ERα degradation (14, 50). I3C treatment also affected the expression of other ERα-responsive genes, including those coding for insulin-like growth factor-1 receptor (IGFR1) and insulin receptor substrate-1 (IRS-1), involved in cell proliferation and deregulated in breast cancer (**Figure 5**) (51).

DNA adduct formation
Estrogen-dependent signaling pathways
Estrogen-dependent proliferation, invasion, metastasis

Overview of the anti-estrogenic actions of indole-3-carbinol (I3C) and 3,3'-diindolylmethane (DIM). *AhR, aryl hydrocarbon receptor; CYP, cytochrome P450; ERα, estrogen receptor α; ESR1, gene encoding ERα.*

[Figure 5 - Click to Enlarge]

Modulation of cell-signaling pathways

I3C and condensation derivatives have been found to affect multiple signaling pathways that are often deregulated in cancer cells. Below are some examples illustrating how I3C, DIM, or ICZ may influence cell proliferation, apoptosis, migration, invasion, angiogenesis, and immunity by targeting specific signaling pathways (23).

Induction of cell cycle arrest and apoptosis

Once a cell divides, it passes through a sequence of stages — collectively known as the cell cycle — before it divides again. Following DNA damage, the cell cycle can be transiently arrested at damage checkpoints, which allows for DNA repair or activation of pathways leading to cell death (apoptosis) if the damage is irreparable (52). Defective cell cycle regulation may result in the propagation of mutations that contribute to the development of cancer. In addition, unlike normal cells, cancerous cells lose their ability to respond to death signals that initiate apoptosis.

I3C-induced downregulation of the phosphatidylinositol 3-kinase (PI3K)/serine-threonine kinase (Akt) cell survival signaling pathway in mice with nasopharyngeal carcinoma resulted in inhibition of cell proliferation and induction of apoptosis (53). Inactivation of the Wnt/β-catenin signaling pathway in DIM-treated colon cancer cells decreased the expression of downstream targets, c-myc and cyclin D1, that promote cell proliferation and survival (54). In prostate cancer cells, I3C opposed the anti-apoptotic effect of epidermal growth factor (EGF) by limiting EGF receptor autophosphorylation (activation) and reducing EGF-induced activation of the PI3K/Akt signaling pathway and expression of the pro-survival target molecules, Bcl-x(L) and BAD (55). In another study, DIM caused apoptosis of prostate cancer cells by stimulating p38 mitogen-activated protein kinase (p38 MAPK)-induced upregulation of tumor suppressor p75^{NTR} (56). The anti-proliferative effect of DIM in cancer cells has also been linked to the inhibition of histone deacetylase (HDAC) activity. Specifically, DIM was found to reverse HDAC-mediated epigenetic silencing of genes coding for key regulators of the cell cycle (57, 58). A recent genome-wide analysis of DNA methylation also showed that DIM could reverse aberrant promoter methylation in prostate cancer cells, at least partly through downregulating the expression of DNA methyltransferases (DNMTs) (59).

Inhibition of cell migration and invasion

The epithelial-to-mesenchymal transition (EMT) describes a process of epithelial cell transformation whereby cells lose their polarity and adhesion properties while gaining migratory and invasive properties through the expression of mesenchymal genes. Inhibition of EMT by I3C and ICZ in breast cancer cells has been associated with upregulation of an epithelial marker, E-cadherin, and downregulation of vimentin, focal adhesion kinase (FAK), and matrix metalloproteins (MMPs) — proteins and enzymes known to promote migration (60). DIM also inhibited migration and invasion of liver cancer cells *in vitro* and *in vivo* through inactivating the FAK signaling pathway (61). Moreover, DIM has been shown to reverse methylation-associated dysregulation of genes involved in cell adhesion, chemotaxis, and inflammation that contributes to cancer progression (59). DIM was able to inhibit lung metastasis in mice with liver (61) or mammary tumors (62).

Inhibition of angiogenesis

To fuel their rapid growth, invasive tumors must also develop new capillaries from preexisting blood vessels by a process known as angiogenesis. I3C inhibited lipopolysaccharide (LPS)-induced macrophage activation and secretion of proangiogenic molecules, such as nitric oxide (NO), vascular endothelial growth factor (VEGF), interleukin-6 (IL-6), and MMP-9, and prevented the formation of capillary-like structures from co-cultured human umbilical endothelial cells (63). Similarly, I3C inhibited capillary-like tube formation from phorbol myristate acetate (PMA)-stimulated endothelial cells (64). DIM also blocked PMA-induced angiogenic activities in human umbilical endothelial cells (65).

Regulation of inflammation and cell-mediated immunity

Uncontrolled inflammation has been associated with several chronic diseases, including cancer. In the mouse ear edema model, 12-*O*-tetradecanoylphorbol-13-acetate (TPA)-induced upregulation of pro-inflammatory mediators, such as cyclooxygenase-2 (COX-2) and inducible nitric oxide synthase (iNOS), has been found to be mitigated by DIM treatment (66). Nuclear factor-kappa B (NF-κB) is a major transcription factor regulating the expression of many pro-inflammatory genes like those coding for COX-2 and iNOS. Specifically, DIM inhibited TPA-induced activation of kinases (inhibitor of kappa B kinase [IκK] and extracellular signal-regulated kinase [ERK]) that control the transcriptional activity of NF-κB (66). In addition, recent animal studies showed that I3C and/or DIM could modulate cell-mediated immune response in experimental autoimmune encephalomyelitis (67), staphylococcal enterotoxin-induced lung inflammation (68), and delayed-type hypersensitivity (69). Specifically, I3C and/or DIM differentially regulated T-cell subpopulations via the activation or suppression of microRNA-dependent pathways controlling cell cycle progression and apoptosis.

Transplacental cancer prevention

The inclusion of I3C in the maternal diet was found to protect the offspring from lymphoma and lung tumors induced by dibenzo[*a*]pyrene, a polycyclic aromatic hydrocarbon (70, 71). Polycyclic aromatic hydrocarbons are chemical pollutants formed during incomplete combustion of organic substances, such as coal, oil, wood, and tobacco (72).

However, the physiological relevance of cell culture and animal studies to human health is unclear since little or no I3C is available to tissues after oral administration (see Metabolism and Bioavailability) (6).

Disease Prevention

Cancer

Some observational studies provide some support for the hypothesis that higher intakes of cruciferous vegetables are associated with lower risk for some types of cancer (see the article on Cruciferous Vegetables) (1). Cruciferous vegetables are relatively good sources of nutrients that may have protective effects against cancer, including vitamin C, folate, selenium, carotenoids, and fiber. In addition, glucosinolates can be hydrolyzed to a variety of potentially protective isothiocyanates, in addition to indole-3-carbinol (see the article on Isothiocyanates). Consequently, evidence for an inverse association between cruciferous vegetable intake and cancer risk provides relatively little information about the specific effects of indole-3-carbinol on cancer risk.

At present, the effects of I3C or DIM supplementation on cancer risk in humans are not known.

Disease Treatment

Human papilloma virus infection-related diseases

Cervical intraepithelial neoplasia

Infection with certain strains of human papilloma virus (HPV) is an important risk factor for cervical cancer (73). Transgenic mice that express cancer-promoting HPV genes develop cervical cancer with chronic 17β-estradiol administration. In this model, feeding I3C markedly reduced the number of mice that developed cervical cancer (74). A small placebo-controlled trial in women examined the effect of oral I3C supplementation on the progression of precancerous cervical lesions classified as cervical intraepithelial neoplasia (CIN) 2 or CIN 3 (75). After 12 weeks, four out of the eight women who took 200 mg/day had complete regression of CIN, and four out of the nine who took 400 mg/day had complete regression; none of the 10 women who took a placebo had complete regression. HPV was present in 7 out of the 10 women in the placebo group, seven out of eight women in the 200 mg I3C group, and eight out of nine women in the 400 mg I3C group (75). However compared to placebo, oral supplementation with DIM (2 mg/kg/day) for 12 weeks in 64 women with CIN 2 or CIN 3 lesions failed to improve clinical parameters during a one-year follow-up period (76). In another six-month randomized, double-blind controlled trial, DIM supplementation (150 mg/day) failed to promote HPV clearance and prevent CIN progression in 551 women with low-grade cell abnormalities in cervical smears (77).

Although oral supplementation of I3C or DIM appears relatively safe and well tolerated, results obtained with I3C are only preliminary, and interventions with DIM failed to show preventative or therapeutic efficacy in women with precancerous lesions of the cervix. The intravaginal administration of DIM in the form of suppositories may prove to be a more effective approach to reverse CIN in women (78).

Vulvar intraepithelial neoplasia

HPV infection has also been associated with vulvar intraepithelial neoplasia (VIN), a precancerous condition that may progress to vulval cancer (79). A small randomized trial in 12 women with VIN found that supplementation with 200 mg/day or 400 mg/day of I3C for six months improved overall symptoms, as well as lesion size and appearance (80). Additional trials are necessary to determine whether I3C might be an effective treatment for VIN.

Recurrent respiratory papillomatosis

Recurrent respiratory papillomatosis (RRP) is a rare disease of children and adults, characterized by generally benign growths (papillomas) in the respiratory tract, which are caused by HPV infection (81). These papillomas occur most commonly on or around the vocal cords in the larynx (voice box), but they may also affect the trachea, bronchi, and lungs. The most common treatment for RRP is surgical removal of the papillomas. Since papillomas often recur, adjunct treatments may be used to help prevent or reduce recurrences (82). In immune-compromised mice transplanted with HPV-infected laryngeal tissue, only 25% of the mice fed I3C developed laryngeal papillomas compared to 100% of the control mice (83). In a small observational study of RRP patients, increased ratios of urinary 2HE$_1$:16HE$_1$ resulting from increased cruciferous vegetable consumption were associated with less severe RRP (84). In an uncontrolled pilot study, the effect of daily I3C supplementation (400 mg/day for adults and 10 mg/kg daily for children) on papilloma recurrence has been examined in RRP patients (85). Over a five-year follow-up period, 11 of the original 49 patients experienced no recurrence, 10 experienced a reduction in the rate of recurrence, 12 experienced no improvement, and 12 were lost to follow-up (86). I3C given for 6 months to 3 years to five children with an aggressive form of the disease halted the growth of the papillomas in three children after two years of treatment (87). In some patients, I3C may be an effective adjunct treatment to reduce the growth or recurrence of respiratory papillomas.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is an autoimmune disorder characterized by chronic inflammation that may result in damage to the joints, skin, kidneys, heart, lungs, blood vessels, or brain (88). Estrogen is thought to play a role in the pathology of SLE because the disorder is much more common in women than men, and its onset is most common during the reproductive years when endogenous estrogen levels are highest (89). The potential for I3C supplementation to shift endogenous estrogen metabolism toward the less estrogenic metabolite 2HE$_1$, and away from the highly estrogenic metabolite 16HE$_1$ (see Anti-estrogenic activities), led to interest in its use in SLE (35). In an animal model of SLE, I3C feeding decreased the severity of kidney disease and prolonged survival (90). A small uncontrolled trial of I3C supplementation (375 mg/day) in female SLE patients found that I3C supplementation increased urinary 2HE$_1$:16HE$_1$ ratios, but the trial found no significant change in SLE symptoms after three months (90). Controlled clinical trials are needed to determine whether I3C supplementation could have beneficial effects in SLE patients.

Sources

Food sources

Glucobrassicin, the glucosinolate precursor of I3C, is found in a number of cruciferous vegetables, including broccoli, Brussels sprouts, cabbage, cauliflower, collard greens, kale, kohlrabi, mustard greens, radish, rutabaga, and turnip (91, 92). Although glucosinolates are present in relatively high concentrations in cruciferous vegetables, glucobrassicin makes up only about 8%-12% of the total glucosinolates (93). Total glucosinolate contents of selected cruciferous vegetables are presented in **Table 1**. However, the amount of total glucosinolates and the amount of indole-3-carbinol formed from glucobrassicin in food is variable and depends, in part, on the processing and preparation of foods (for more detailed information, see the article on Cruciferous Vegetables).

Table 1. Glucosinolate Content of Selected Cruciferous Vegetables (94)

Food (raw)	Serving	Total Glucosinolates (mg)
Brussels sprouts	½ cup	104
Garden cress	½ cup	98
Mustard greens	½ cup, chopped	79
Kale	1 cup, chopped	67
Turnip	½ cup, cubes	60
Cabbage, savoy	½ cup, chopped	35
Watercress	1 cup, chopped	32
Kohlrabi	½ cup, chopped	31
Cabbage, red	½ cup, chopped	29
Broccoli	½ cup, chopped	27
Horseradish	1 tablespoon (15 g)	24
Cauliflower	½ cup, chopped	22
Bok choi (pak choi)	½ cup, chopped	19

Supplements

Indole-3-Carbinol (I3C)

I3C is available without a prescription as a dietary supplement, alone or in combination products. Dosage ranges between 200 mg/day and 800 mg/day (95). I3C supplementation increased urinary 2HE$_1$ concentrations in adults at doses of 300 to 400 mg/day (39). I3C doses of 200 mg/day or 400 mg/day improved the regression of cervical intraepithelial neoplasia (CIN) in a preliminary clinical trial (75). I3C in doses up to 400 mg/day has been used to treat recurrent respiratory papillomatosis (see Disease Treatment) (85, 86).

3,3'-Diindolylmethane (DIM)

DIM is available without a prescription as a dietary supplement, alone or in combination products. In a small clinical trial, DIM supplementation at a dose of 108 mg/day for 30 days increased urinary 2HE$_1$ excretion in postmenopausal women with a history of breast cancer (34).

Safety

Adverse effects

Slight increases in the serum concentrations of the liver enzyme, alanine aminotransferase (ALT) were observed in two women who took unspecified doses of I3C supplements for four weeks (39). One person reported a skin rash while taking 375 mg/day of I3C (35). High doses of I3C (800 mg/day) have been associated with symptoms of disequilibrium and tremor, which resolved when the dose was decreased (85). In a phase I study in women at high risk for breast cancer, 5 out of 20 participants had gastrointestinal symptoms with single doses ≥600 mg, although others had no adverse effects with single doses up to 1,200 mg (6). No adverse effects were reported with daily consumption of 400 mg of I3C for four weeks (6).

In some animal models, I3C supplementation was found to enhance carcinogen-induced cancer development when given chronically after the carcinogen (96-99). When administered before or at the same time as the carcinogen, oral I3C inhibited tumorigenesis in animal models of cancers of the mammary gland (100, 101), uterus (102), stomach (103), colon (104, 105), lung (106), and liver (107, 108). Although the long-term effects of I3C supplementation on cancer risk in humans are not known, the contradictory results of animal studies have led several experts to caution against the widespread use of I3C and DIM supplements in humans until their potential risks and benefits are better understood (99, 109, 110).

Pregnancy and lactation

The safety of I3C or DIM supplements during pregnancy or lactation has not been established (95).

Drug interactions

No drug interactions with I3C or DIM supplementation in humans have been reported. However, preliminary evidence that I3C and DIM can increase the activity of CYP1A2 (111, 112) suggests the potential for I3C or DIM supplementation to decrease serum concentrations of medications metabolized by CYP1A2 (113). Both I3C and DIM modestly increase the activity of CYP3A4 in rats when administered chronically (114). This observation raises the potential for adverse drug interactions in humans since CYP3A4 is involved in the metabolism of approximately 60% of therapeutic drugs.

The acidic environment of the stomach allows I3C molecules to condense and generate a number of biologically active I3C oligomers (**Figure 2**). Drugs that block the production of stomach acids, like antacids, Histamine$_2$ (H$_2$) receptor antagonists, and proton-pump inhibitors, would likely prevent the generation of DIM and ICZ. However, it is not known whether these drugs limit the biological activities attributed to I3C and its derivatives (95).

Summary

- Isothiocyanates are derived from the hydrolysis of glucosinolates — sulfur-containing compounds found in cruciferous vegetables. *(More information)*
- Each glucosinolate forms a different isothiocyanate when hydrolyzed. For example, broccoli is a good source of glucoraphanin, the glucosinolate precursor of sulforaphane, and sinigrin, the glucosinolate precursor of allyl isothiocyanate. *(More information)*
- Absorbed isothiocyanates are rapidly conjugated to glutathione in the liver, and then sequentially metabolized in the mercapturic acid pathway, before being excreted in the urine. *(More information)*
- Isothiocyanates may modulate the expression and activity of biotransformation enzymes that are involved in the metabolism and elimination of xenobiotics (e.g., carcinogens) from the body. In cultured cells and animal models, isothiocyanates also exhibited antioxidant and anti-inflammatory activities and interfered with numerous cancer-related targets and pathways. *(More information)*
- Although high intakes of cruciferous vegetables have been associated with a lower risk for cancer, there is insufficient evidence that exposure to isothiocyanates through cruciferous vegetable consumption decreases cancer risk. *(More information)*
- Glucosinolates are present in relatively high concentrations in cruciferous vegetables, but the amounts of isothiocyanates formed from glucosinolates in foods are variable and depend partly on food processing and preparation. *(More information)*

Introduction

Cruciferous vegetables, such as broccoli, cabbage, and kale, are rich sources of sulfur-containing compounds called glucosinolates (see the article on Cruciferous Vegetables). Isothiocyanates are biologically active hydrolysis (breakdown) products of glucosinolates. Cruciferous vegetables contain a variety of glucosinolates, each of which forms a different isothiocyanate when hydrolyzed (**Figure 1**) (1). For example, broccoli is a good source of glucoraphanin, the glucosinolate precursor of sulforaphane, and sinigrin, the glucosinolate precursor of allyl isothiocyanate (AITC) (see Food sources) (2). Watercress is a rich source of gluconasturtiin, the precursor of phenethyl isothiocyanate (PEITC), while garden cress is rich in glucotropaeolin, the precursor of benzyl isothiocyanate (BITC) (see Food sources). At present, scientists are interested in the cancer-preventive activities of vegetables that are rich in glucosinolates (see the article on Cruciferous Vegetables), as well as individual isothiocyanates (3).

Metabolism and Bioavailability

Metabolism

The hydrolysis of glucosinolates, which is catalyzed by a class of enzymes called myrosinases (β-thioglucosidases), leads to the formation of breakdown compounds, such as thiocyanates, isothiocyanates, indoles, oxazolidine-2-thiones (e.g., goitrin), epithionitrile, and nitrile (see the article on Cruciferous Vegetables). In intact plant cells, myrosinase is physically separated from glucosinolates. Yet, when plant cells are damaged, myrosinase is released and comes in contact with glucosinolates, catalyzing their conversion into highly reactive metabolites that impart a pungent aroma and spicy (some say bitter) taste. Likewise, when raw cruciferous vegetables are chopped during the food preparation process, glucosinolates are rapidly hydrolyzed by myrosinase, generating metabolites that are then absorbed in the proximal intestine. In contrast, cooking cruciferous vegetables before consumption inactivates myrosinase, thus preventing the breakdown of glucosinolates. However, lightly cooking (i.e., light steam for <5 minutes) will preserve some of the myrosinase and allow for isothiocyanate conversion. A small fraction of intact glucosinolates may be absorbed in the small intestine, but a large proportion reaches the colon (4). In the colon, myrosinase produced by the microbiota can catalyze the generation of a wide range of metabolites from glucosinolates, depending on the pH and the presence of cofactors (4, 5).

The hydrolysis of glucosinolates at neutral pH results in the formation of unique isothiocyanates (**Figure 1**). For example, sinigrin, glucoraphanin, glucotropaeolin, and gluconasturtiin are the glucosinolate precursors of AITC, sulforaphane, BITC, and PEITC, respectively (**Figure 1**). Once absorbed, glucosinolate-derived isothiocyanates (like sulforaphane) are promptly conjugated to glutathione by a class of phase II detoxification enzymes known as glutathione *S*-transferases (GSTs) in the liver, and then sequentially metabolized in the mercapturic acid pathway (**Figure 2**). This mechanism is meant to increase the solubility of isothiocyanates, thereby promoting a rapid excretion in the urine. Using sulforaphane as the model isothiocyanate, it has indeed been established that its metabolites — sulforaphane-glutathione, sulforaphane-cysteine-glycine, sulforaphane-cysteine, and sulforaphane N-acetylcysteine — collectively known as dithiocarbamates (**Figure 2**), are ultimately excreted in the urine (4).

[Figure 2 - Click to Enlarge]

Bioavailability

The composition and content of glucosinolates in cruciferous vegetables are relatively stable but depend on the genus and species and can vary with plant growing and post-harvest storage conditions and culinary processing (6, 7). Since most cruciferous vegetables are cooked prior to eating, bacterial myrosinase in the gut, rather than plant myrosinase, is responsible for the initial step in glucosinolate degradation (**Figure 2**). In a feeding study involving 45 healthy subjects, the mean conversion rate of glucosinolates (of which 85% was glucoraphanin) to dithiocarbamates over a 24-hour period was estimated to be around 12% with wide variations among participants (range, 1.1 to 40.7%) (6). In contrast, 70%-75% of ingested isothiocyanates were found to be metabolized to dithiocarbamates. Therefore, following the ingestion of cooked cruciferous vegetables, the conversion of glucosinolates into isothiocyanates by gut bacteria appears to be a limiting step in the generation of dithiocarbamates (6). However, differences in individuals' capacity to metabolize glucosinolates have not been linked to differences in gut microbiota composition (8).

Biological Activities

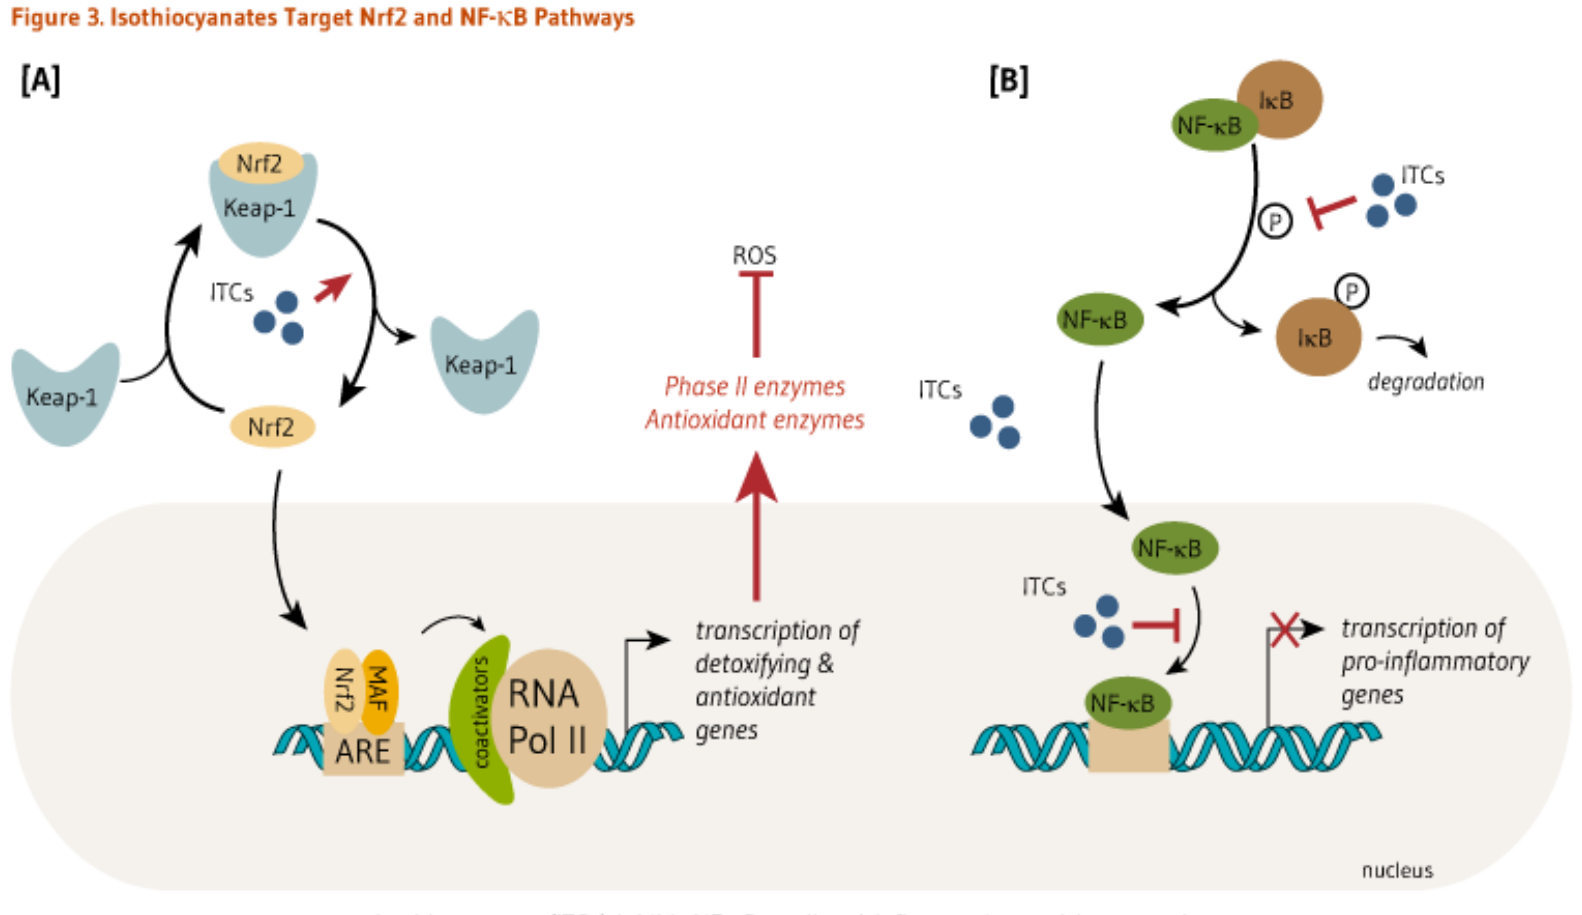
Antioxidant activity

Many isothiocyanates, particularly sulforaphane, have been shown to induce the expression of antioxidant enzymes via the activation of the nuclear factor E2-related factor 2 (Nrf2)-dependent pathway (9, 10). Briefly, Nrf2 is a transcription factor that is bound to the protein Kelch-like ECH-associated protein 1 (Keap1) in the cytosol (**Figure 3**). Keap1 responds to oxidative stress signals or chemical inducers by freeing Nrf2. Isothiocyanates can react with sulfhydryl residues of Keap1, causing the release of Nrf2. Nrf2 can then translocate to the nucleus and bind to the antioxidant response element (ARE) located in the promoters of genes coding for antioxidant/detoxifying enzymes and scavengers. Nrf2/ARE-dependent genes code for several mediators of the antioxidant response, including glutathione S-transferases (GSTs), thioredoxin, NAD(P)H quinone oxidoreductase 1 (NQO-1), and heme oxygenase 1 (HO-1) (11).

In numerous animal models, sulforaphane (often administered ip, iv, or sc, rather than po) was shown to exert protective effects on many tissues and organs by activating the Nrf2/ARE-dependent pathway (12). For example, sulforaphane reduced contrast agent-induced kidney damage in rats by increasing Nrf2 nuclear translocation and upregulating the expression of HO-1 and NQO-1 (13). Upregulation of the Nrf2 pathway by sulforaphane also attenuated oxidative damage-induced vascular endothelial cell injury in a mouse model of type 2 diabetes mellitus (14). In a rat model of hepatic ischemia reperfusion injury — whereby cellular damage is caused by the restoration of oxygen delivery to a hypoxic liver — pre-treatment with sulforaphane limited the reduction in glutathione (GSH) and the antioxidant enzymes, superoxide dismutase (SOD) and GSH peroxidase (GPx). Sulforaphane also upregulated the expression of Nrf2, NQO-1, and HO-1, and decreased ischemic death and apoptosis of liver cells (15).

Human studies are limited. In a placebo-controlled study, oral sulforaphane (in the form of broccoli sprout homogenate) increased the expression of NQO-1 and HO-1 in the upper airway within two hours of ingestion (16). Yet, in a recent trial in patients with chronic obstructive pulmonary disease (COPD), oral administration of sulforaphane for four weeks failed to induce the expression of Nrf2, NQO-1, and HO-1 in alveolar macrophages, bronchial epithelial cells, or peripheral blood mononuclear cells (17).

Figure 3. Isothiocyanates Target Nrf2 and NF-κB Pathways



Isothiocyanates (ITCs) inhibit NF-κB-mediated inflammation and increase the expression of phase II detoxifying/antioxidant enzymes via the Nrf2 signaling pathway. [A] ITCs induce the nuclear translocation of Nrf2 and increase the expression of Nrf2 target genes coding for phase II enzymes and antioxidant enzymes. [B] ITCs may prevent (1) the phosphorylation of NF-κB inhibitor, IκB; (2) the nuclear translocation of NF-κB; and (3) the transcriptional activity of NF-κB. *ARE, antioxidant response element; IκB, inhibitor of kappa B; Keap-1, Kelch-like ECH-associated protein 1; MAF, Nrf2 transcriptional cofactor; Nrf2, nuclear factor E2-related factor 2; NF-κB, nuclear factor kappa B; RNA Pol II, RNA polymerase II; ROS, reactive oxygen species.*

[Figure 3 - Click to Enlarge]

Anti-inflammatory activity

The therapeutic potential of sulforaphane has also been linked to its capacity to target pro-inflammatory pathways. Sulforaphane was found to attenuate pancreatic injury in a mouse model of acute pancreatitis by stimulating Nrf2-induced antioxidant enzymes (18). Concomitantly, sulforaphane significantly reduced the nuclear translocation of the pro-inflammatory transcription factor nuclear factor (NF)-κB in pancreatic acinar cells, downregulating the expression of NF-κB target genes that code for pro-inflammatory mediators, such as tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1β), and IL-6 (**Figure 3**) (18). Through inhibiting the NF-κB pathway, sulforaphane also targets other mediators of the inflammatory response, including the enzymes cyclooxygenase-2 (COX-2), prostaglandin E (PGE) synthase, and inducible nitric oxide synthase (iNOS). Sulforaphane exhibited anti-inflammatory effects in the lungs of mice with lipopolysaccharide (LPS)-induced acute respiratory distress syndrome (ARDS) by downregulating the expression of NF-κB, IL-6, TNF-α and COX-2, as well as decreasing production of nitric oxide (NO) and PGE2 (19). Other isothiocyanates have been shown to prevent the degradation of the NF-κB inhibitor, IκB, the nuclear translocation of NF-κB, and/or the transcriptional activity of NF-κB *in vitro* or in cultured cells (**Figure 3**) (20), which all can lead to a decrease in inflammatory responses.

The modulation of Nrf2 and NF-κB signaling pathways by isothiocyanates is especially relevant to the prevention of cancer because both oxidative stress and inflammation are significant contributors in the development and progression of cancer.

Anticancer activity

Biotransformation enzymes play important roles in the metabolism and elimination of a variety of chemicals, including drugs, toxins, and carcinogens. In general, phase I metabolizing enzymes catalyze reactions that increase the reactivity of hydrophobic (fat-soluble) compounds, preparing them for reactions catalyzed by phase II biotransformation enzymes. Reactions catalyzed by phase II enzymes generally increase water solubility and promote the elimination of the compound from the body (21).

Inhibition of phase I biotransformation enzymes

Isothiocyanates have been found to modulate the activity of phase I biotransformation enzymes, especially those of the cytochrome P450 (CYP) family. Using a primary rat hepatocyte-based model, both aliphatic (e.g., sulforaphane, AITC) and aromatic (e.g., BITC, PEITC) isothiocyanates (at 20-40 μM) have been found to downregulate CYP3A2 mRNA expression, as well as the activity of benzyloxyquinoline debenzylase, a marker of CYP3As (22). Aromatic isothiocyanates were also able to upregulate CYP1A1 and CYP1A2 mRNA expression and the activity of ethoxyresorufin-O-deethylase (EROD), a marker of CYP1A1/2 activities (22). In this model, sulforaphane inhibited EROD activity, yet failed to affect CYP1A1/2 mRNA expression (22). Using human liver microsomes, it was also recently reported that sulforaphane metabolites (0-200 μM) had little-to-no effect on the activities of CYP1A2, CYP2B6, CYP2D6, and CYP3A4 (23). The ability of PEITC to alter the expression and activity of CYP enzymes has been generally associated with a protective effect against (pro)carcinogen-induced tumor development in animal experiments (reviewed in 24). Increasing the activity of biotransformation enzymes may be beneficial if the elimination of potential carcinogens or toxins is enhanced. Yet, some procarcinogens require phase I enzymes in order to become active carcinogens capable of binding DNA and forming cancer-causing DNA adducts. Inhibition of specific CYP enzymes involved in carcinogen activation has been found to prevent the development of cancer in animal models (3).

Induction of phase II detoxifying enzymes

Many isothiocyanates are potent inducers of phase II detoxifying enzymes, including GSTs, UDP-glucuronosyl transferases (UGTs), NQO1, and glutamate cysteine ligase (GCL), that protect cells from DNA damage by carcinogens and reactive oxygen species (ROS) (25). The genes for these and other phase II enzymes contain AREs and are therefore under the control of Nrf2 (see Antioxidant activity). Limited data from clinical trials suggest that glucosinolate-rich foods can increase phase II enzyme activity in humans. When smokers consumed 170 g/day (6 oz/day) of watercress, urinary excretion of glucuronidated nicotine metabolites increased significantly, suggesting UGT activity increased (26). Brussels sprouts are rich in a number of glucosinolates, including precursors of AITC and sulforaphane. Consumption of 300 g/day (11 oz/day) of Brussels sprouts for one week significantly increased plasma and intestinal GST concentrations in nonsmoking men (27, 28).

Induction of cell cycle arrest and apoptosis

After a cell divides, it passes through a sequence of stages — collectively known as the cell cycle — before dividing again. Following DNA damage, the cell cycle can be transiently arrested to allow for DNA repair or activation of pathways leading to programmed cell death (apoptosis) when the damage cannot be repaired (29). Defective cell cycle regulation and pro-survival mechanisms may result in the propagation of mutations that contribute to the development of cancer. Isothiocyanates have been found to modulate the expression of the cell cycle regulators, cyclins and cyclin-dependent kinases (CDK), as well as to trigger apoptosis in a number of cancer cell lines (20). In a mouse model of colorectal cancer, oral administration of PEITC reduced both the number and size of polyps; these changes were associated with activation of the CDK inhibitor, p21, inhibition of various cyclins (A, D1, and E), and induction of apoptosis (30). In a transgenic prostate adenocarcinoma mouse model, BITC limited the progress of prostatic intraepithelial neoplasia (PIN) to a well-differentiated carcinoma (31). This was related to a decreased expression of Ki67 (a marker of cell proliferation) and a downregulation of cyclin A, cyclin D1, and CDK2, which regulate cell cycle progression (31).

Inhibition of cell migration and invasion

The epithelial-to-mesenchymal transition (EMT) describes a process of epithelial cell transformation whereby cells lose their polarity and adhesion properties while gaining migratory and invasive properties through the expression of mesenchymal genes. Inhibition of the EMT by sulforaphane in thyroid cancer cells has been associated with upregulation of an epithelial marker, E-cadherin, and downregulation of a transcription factor (SNAI2), a filament protein (vimentin), and various enzymes (matrix metalloprotein [MMP]-2 and MMP-9) known to contribute to EMT and promote migration (32). In a xenograft mouse model of breast cancer, BITC inhibited high fat diet-driven promotion of breast tumor growth, as well as lung and liver metastasis (33). This study suggested that BITC might prevent the infiltration of macrophages in the tumor environment (33). In another model of breast tumor metastasis, PEITC inhibited the migration of tumor cells to the brain after injection into the heart of mice, limiting the growth of metastatic brain tumors (34).

Inhibition of angiogenesis

To fuel their rapid growth, invasive tumors must also develop new capillaries from preexisting blood vessels by a process known as angiogenesis. Isothiocyanates have been shown to prevent the formation of capillary-like structures from human umbilical endothelial cells (reviewed in 35). Isothiocyanates likely inhibit the expression and function of hypoxia inducible factors (HIFs) that control angiogenesis, as reported in endothelial cells and malignant cell lines (35).

Epigenetic regulation of gene expression

In the nucleus of a cell, DNA is coiled around proteins called histones, thereby forming the chromatin. The N-terminal tails of histones are targets for multiple modifications, including phosphorylation, methylation, acetylation, ubiquitination, poly ADP ribosylation, and sumoylation. Histone modification patterns have differential effects on chromatin structure, and, in synergy with DNA methylation, are implicated in the regulating expression of the genome (36). Within gene regulatory regions, the acetylation of lysine residues of histone tails has been correlated with activation of transcription. Conversely, the deacetylation of histones by histone deacetylases (HDAC) restricts access of transcription factors to the DNA and suppresses transcription. Because abnormal epigenetic marks disrupt the expression of specific tumor suppressor genes in cancer cells, compounds that re-induce their transcription, like those inhibiting HDACs, can potentially promote differentiation and apoptosis in transformed (precancerous) cells (37).

Isothiocyanates have been found to inhibit HDAC expression and/or activity in cultured cancer cells (38-43). Moreover, *in vivo* evidence for HDAC inhibition by sulforaphane came from a mouse model using prostate cancer xenografts (44). In humans, HDAC activity was reduced in blood cells following ingestion of 68 g (one cup) of sulforaphane-rich broccoli sprouts (44). Isothiocyanates may also affect microRNA-mediated gene silencing. In bladder cancer cells, E-cadherin induction by sulforaphane was partly due to the upregulation of miR-200c expression resulting in the miR-200c-dependent suppression of ZEB-1, a transcriptional repressor of E-cadherin (45). PEITC inhibited androgen receptor (AR) transcriptional activity in prostate cancer cells by repressing miR-141 expression and miR-141-mediated downregulation of small heterodimer partner (shp), a repressor of AR (46).

Antibacterial activity

Bacterial infection with *Helicobacter pylori* is associated with a marked increase in the risk of peptic ulcer disease and gastric cancer (47). In the test tube and in tissue culture, purified sulforaphane inhibited the growth and killed multiple strains of *H. pylori*, including antibiotic resistant strains (48). In an animal model of *H. pylori* infection, sulforaphane administration for five days eradicated *H. pylori* from 8 out of 11 xenografts of human gastric tissue implanted in immune-compromised mice (49). In another *H. pylori*-infected mouse model, a functional Nrf2 pathway was found to be required for the reduction of gastric inflammation and infection in mice fed broccoli sprouts (50). In a small clinical trial, consumption of up to 56 g/day (2 oz/day) of glucoraphanin-rich broccoli sprouts for one week was associated with *H. pylori* eradication in only three out of nine gastritis patients (51). In another trial, daily consumption of 70 g/day (~2-3 servings/day) of glucoraphanin-rich broccoli sprouts for two months significantly reduced markers of inflammation and infection in *H. pylori*–infected volunteers compared to those who consumed alfalfa sprouts (50). However, the extent to which glucoraphanin was converted to sulforaphane in broccoli sprout-fed participants was not measured.

Disease Prevention

Cancer

Isothiocyanates are thought to play a prominent role in the potential anticancer and cardiovascular benefits associated with cruciferous vegetable consumption (52, 53). Genetic variations in the sequence of genes coding for GSTs may affect the activity of GSTs. Such variations have been identified in humans. Specifically, null variants of the *GSTM1* and *GSTT1* alleles contain large deletions, and individuals who inherit two copies of the *GSTM1*-null or *GSTT1*-null alleles cannot produce the corresponding GST enzymes (54). It has been proposed that a reduced GST activity in these individuals would slow the rate of excretion of isothiocyanates, thereby increasing tissue exposure to isothiocyanates after cruciferous vegetable consumption (55). In addition, GSTs are involved in "detoxifying" potentially harmful substances like carcinogens, suggesting that individuals with reduced GST activity might also be more susceptible to cancer (56-58). Further, induction of the expression and activity of GSTs and other phase II detoxification/antioxidant enzymes by isothiocyanates is an important defense mechanism against oxidative stress and damage associated with the development of diseases like cancer and cardiovascular disease (11). The ability of glucoraphanin-derived sulforaphane to reduce oxidative stress in different settings is linked to activation of the nuclear factor E2-related factor 2 (Nrf2)-dependent pathway (see Biological Activities). Yet, whether potential protection conferred by isothiocyanates via the Nrf2-dependent pathway is diminished in individuals carrying *GST* null variants is currently unknown. Some, but not all, observational studies have suggested that GST genotypes could influence the associations between cruciferous vegetable consumption and risk of disease (59).

Naturally occurring isothiocyanates and their metabolites have been found to inhibit the development of chemically-induced cancers of the lung, liver, esophagus, stomach, small intestine, colon, and breast in a variety of animal models (20). Although observational studies provide some evidence that higher intakes of cruciferous vegetables are associated with decreased cancer risk in humans (59), it is difficult to determine whether such protective effects are related to isothiocyanates or other factors associated with cruciferous vegetable consumption (see the article on Cruciferous Vegetables). Clinical evidence of a protective effect of isothiocyanates in humans is scarce. For example, in a recent randomized, cross-over intervention, administration of PEITC (40 mg/day for five days) caused a modest, yet significant, 7.7% reduction in the metabolic activation of the tobacco-specific lung carcinogen, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone, in cigarette smokers (60). Another randomized controlled trial in men with biochemically relapsing cancer after radical prostatectomy suggested that prostate-specific antigen (PSA) values tended to increase less in those given daily oral sulforaphane (4.4 or 26.6 mg/day) for six months compared to those receiving the placebo (61). In a recent double-blind, randomized, placebo-controlled trial in women with abnormal mammograms, two-to-eight week consumption of about 250 mg/day of broccoli seed extract (~220 mg of glucoraphanin/day) before surgery failed to affect the expression of markers of proliferation and gene expression, including ki-67, p21, HDACs, and acetylated histones, in breast tissues collected after surgery (62).

Sources

Food sources

Cruciferous vegetables

Cruciferous vegetables, such as bok choi, broccoli, Brussels sprouts, cabbage, cauliflower, horseradish, kale, kohlrabi, mustard, radish, rutabaga, turnip, and watercress, are rich sources of glucosinolate precursors of isothiocyanates (63). Unlike some other phytochemicals, glucosinolates are present in relatively high concentrations in commonly consumed portions of cruciferous vegetables. For example one-half cup of raw broccoli might provide more than 25 mg of total glucosinolates. The glucosinolate content of selected cruciferous vegetables is presented in **Table 1** (64). Note that while the composition and content of glucosinolates in cruciferous vegetables are relatively stable, they depend on the genus and species and can vary greatly with plant growing and post-harvest storage conditions, as well as culinary processing.

Table 1. Glucosinolate Content of Selected Cruciferous Vegetables

Food (raw)	Serving	Total Glucosinolates (mg)
Brussels sprouts	½ cup (44 g)	104
Garden cress	½ cup (25 g)	98
Mustard greens	½ cup, chopped (28 g)	79
Turnip	½ cup, cubes (65 g)	60
Cabbage, savoy	½ cup, chopped (45 g)	35
Kale	1 cup, chopped (67 g)	67
Watercress	1 cup, chopped (34 g)	32
Kohlrabi	½ cup, chopped (67 g)	31
Cabbage, red	½ cup, chopped (45 g)	29
Broccoli	½ cup, chopped (44 g)	27
Horseradish	1 tablespoon (15 g)	24
Cauliflower	½ cup, chopped (50 g)	22
Bok choy (pak choi)	½ cup, chopped (35 g)	19

Table 2 lists vegetables that are relatively good sources of some of the isothiocyanates that are currently being studied for their potential anticancer properties (65).

Table 2. Food Sources of Selected Isothiocyanates and Their Glucosinolate Precursors

Isothiocyanate	Glucosinolate (precursor)	Food Sources
Allyl isothiocyanate (AITC)	Sinigrin	Broccoli, Brussels sprouts, cabbage, horseradish, kohlrabi, mustard, radish
Benzyl isothiocyanate (BITC)	Glucotropaeolin	Cabbage, garden cress, Indian cress
Phenethyl isothiocyanate (PEITC)	Gluconasturtiin	Watercress
Sulforaphane	Glucoraphanin	Broccoli, Brussels sprouts, cabbage, cauliflower, kale

Amounts of isothiocyanates formed from glucosinolates in foods are variable and depend partly on food processing and preparation (see the article on Cruciferous Vegetables). In a recent study that examined total isothiocyanate content in 73 samples from nine types of raw cruciferous vegetables commonly consumed in the US (namely broccoli, cabbage, cauliflower, Brussels sprout, kale, collard green, mustard green, and turnip greens), an average yield of 16.2 μmol/100 g wet weight was reported, with a 41-fold difference of isothiocyanate yield across the vegetables. The lowest mean level of isothiocyanate yield was found with raw cauliflower (1.5 μmol/100 g), while raw mustard greens had the highest yield (61.3 μmol/100g) (66).

Broccoli sprouts

The amount of glucoraphanin, the precursor of sulforaphane, in broccoli seeds remains more or less constant as those seeds germinate and grow into mature plants. Thus, three-day old broccoli sprouts are concentrated sources of glucoraphanin, which contain 10 to 100 times more glucoraphanin by weight than mature broccoli plants (67). Broccoli sprouts that are certified to contain at least 73 mg of glucoraphanin (also called sulforaphane glucosinolate) per 1-oz serving are available in some health food and grocery stores.

Supplements

Dietary supplements containing extracts of broccoli sprouts, broccoli, and other cruciferous vegetables are available without a prescription. Some products are standardized to contain a minimum amount of glucosinolates and/or sulforaphane. However, the bioavailability of isothiocyanates was found to be much lower with the consumption of broccoli supplements devoid of myrosinase than with the consumption of fresh broccoli sprouts. Peak concentrations of sulforaphane metabolites were found to be eight- and five-times greater in plasma and urine, respectively, following fresh broccoli versus supplement consumption (68). Interestingly, total HDAC activity in peripheral blood mononuclear cells (PBMC) of broccoli sprout consumers was reported to be significantly lower than in PBMC of subjects who consumed the supplement (see Biological Activities) (69).

Safety

Adverse effects

No serious adverse effects of isothiocyanates in humans have been reported. The majority of animal studies have found that isothiocyanates inhibited the development of cancer when given prior to the chemical carcinogen (pre-initiation). However, very high intakes of PEITC or BITC (25 to 250 times higher than average human dietary isothiocyanate intakes) have been found to promote bladder cancer in rats when given after cancer initiation by a chemical carcinogen (70). The relevance of these findings to human urinary bladder cancer is not clear, since at least one prospective cohort study found cruciferous vegetable consumption to be inversely associated with the risk of bladder cancer in men (71). Other potential toxic effects reported in rodents have not been corroborated by observations in humans (20).

Pregnancy and lactation

Although high dietary intakes of glucosinolates from cruciferous vegetables are not known to have adverse effects during pregnancy or lactation, there is no information on the safety of purified isothiocyanates or supplements containing high doses of glucosinolates and/or isothiocyanates during pregnancy or lactation in humans.

Drug interactions

Isothiocyanates are not known to interact with any drugs or medications. However, the potential for isothiocyanates to inhibit various isoforms of the cytochrome P450 (CYP) family of enzymes raises the potential for interactions with drugs that are CYP substrates (see Biological Activities). Isothiocyanates may sensitize cancer cells to anticancer drugs and/or increase drug cytotoxicity, as shown in *in vitro* and animal models. Yet, these potential benefits of isothiocyanates in cancer therapy have not been explored in clinical trials (72).

Summary

- Lignans are polyphenolic compounds found in plants. *(More information)*
- Lignan precursors are found in a wide variety of plant-based foods, including seeds, whole grains, legumes, fruit, and vegetables. *(More information)*
- Flaxseeds are the richest dietary source of lignan precursors. *(More information)*
- When consumed, lignan precursors may be converted to the enterolignans, enterodiol and enterolactone, by bacteria that normally colonize the human intestine. *(More information)*
- Enterodiol and enterolactone have weak estrogenic activity but may also exert biological effects through non-estrogenic mechanisms. *(More information)*
- Lignan-rich foods are part of a healthy diet, but the roles of lignans in the prevention of hormone-associated cancers, osteoporosis, and cardiovascular disease are not yet clear. *(More information)*

Introduction

The enterolignans, enterodiol and enterolactone (**Figure 1**), are formed by the action of intestinal bacteria on lignan precursors found in plants (1). Because enterodiol and enterolactone can mimic some of the effects of estrogens, their plant-derived precursors are classified as phytoestrogens. Lignan precursors that have been identified in the human diet include pinoresinol, lariciresinol, secoisolariciresinol, matairesinol, and others (**Figure 2**). Secoisolariciresinol and matairesinol were among the first lignan precursors identified in the human diet and are therefore the most extensively studied. Lignan precursors are found in a wide variety of foods, including flaxseeds, sesame seeds, legumes, whole grains, fruit, and vegetables. While most research on phytoestrogen-rich diets has focused on soy isoflavones, lignans are the principal source of dietary phytoestrogens in the typical Western diet (2, 3).

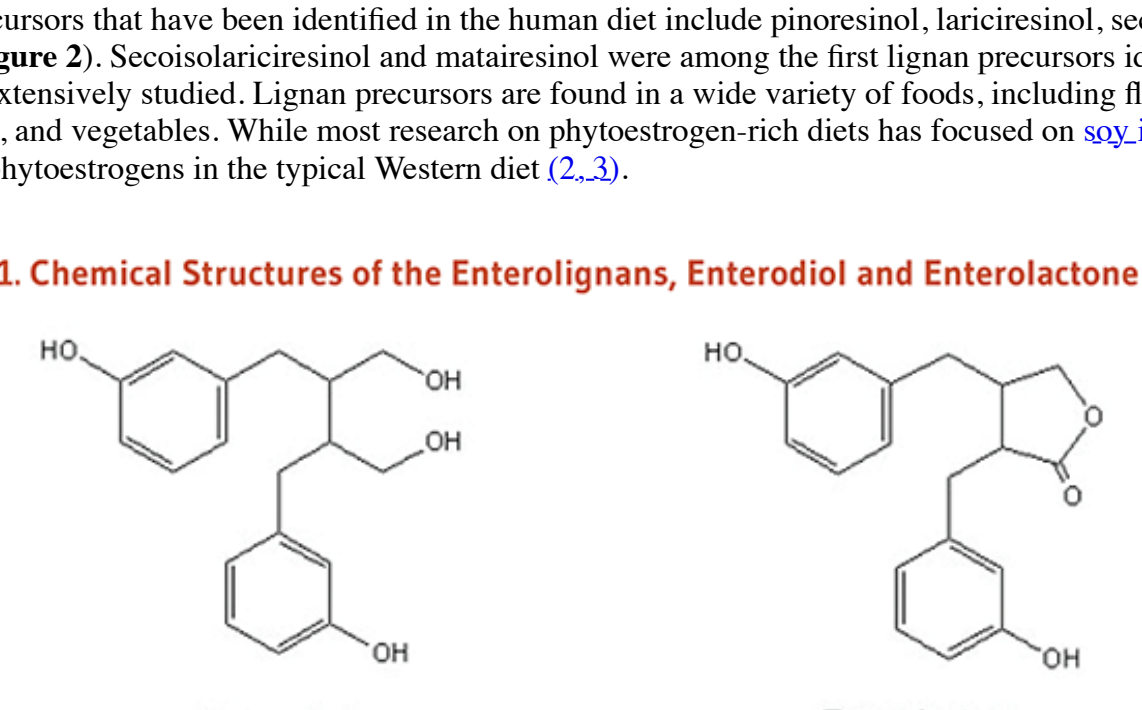

Figure 2. Chemical Structures of Some Dietary Lignan Precursors

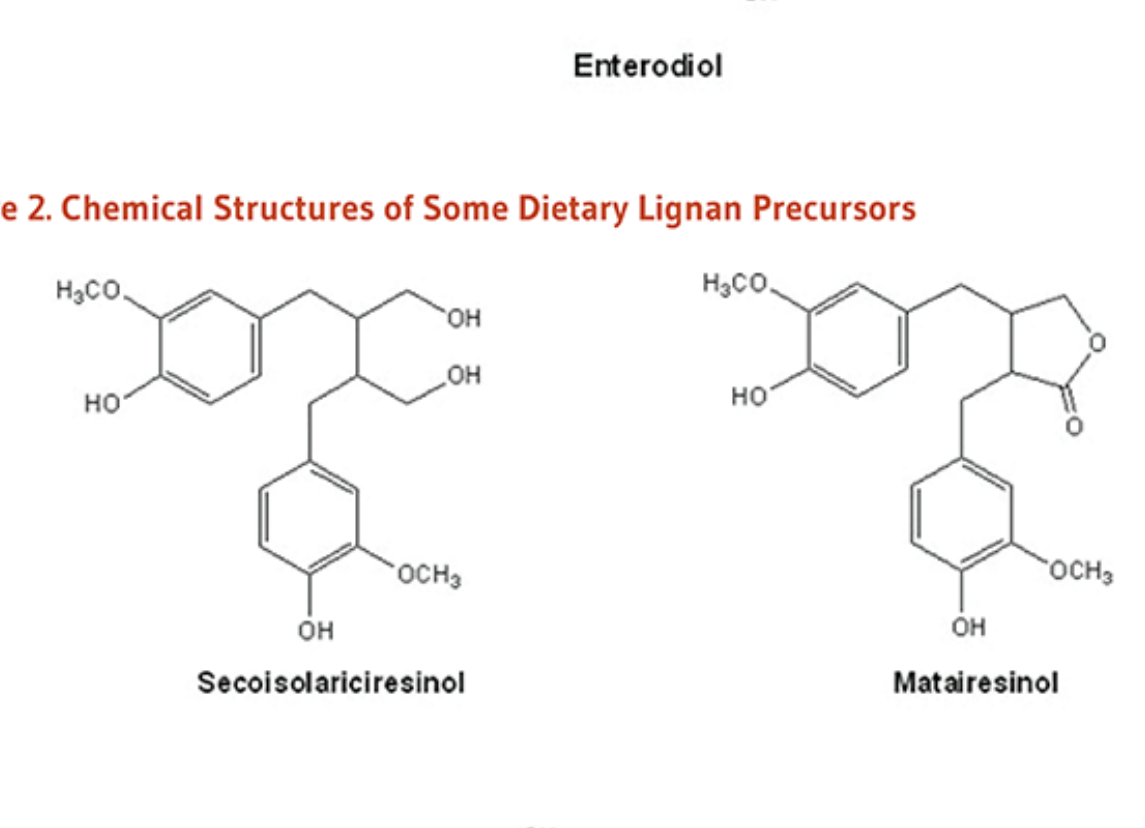


Metabolism and Bioavailability

When plant lignans are ingested, they can be metabolized by intestinal bacteria to the enterolignans, enterodiol and enterolactone, in the intestinal lumen and then absorbed into the bloodstream (4). Enterodiol can also be converted to enterolactone by intestinal bacteria. Thus, enterolactone levels measured in blood and urine reflect the activity of intestinal bacteria in addition to dietary intake of plant lignans. Not surprisingly, antibiotic use has been associated with lower serum enterolactone concentrations (5).

Because data on the lignan content of foods are limited, blood and urinary enterolactone levels are sometimes used as markers of dietary lignan intake. A pharmacokinetic study that measured plasma and urinary levels of enterodiol and enterolactone after a single dose (0.9 mg/kg of body weight) of secoisolariciresinol, the principal lignan in flaxseed, found that at least 40% was available to the body as enterodiol and enterolactone (6). Plasma enterodiol concentrations peaked at 73 nanomoles/liter (nmol/L) an average of 15 hours after ingestion of secoisolariciresinol, and plasma enterolactone concentrations peaked at 56 nmol/L an average of 20 hours after ingestion. Thus, substantial amounts of ingested plant lignans are available to humans in the form of enterodiol and enterolactone.

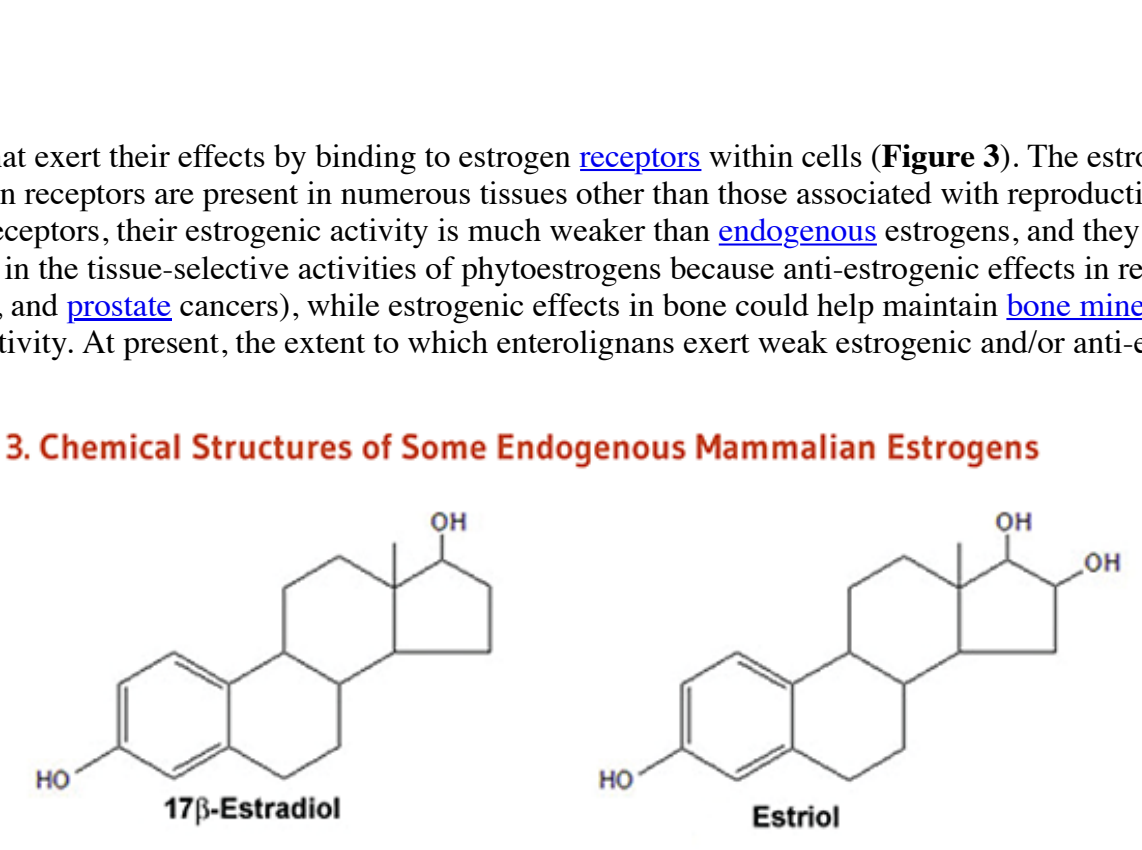
Considerable variation among individuals in urinary and serum enterodiol:enterolactone ratios has been observed in flaxseed feeding studies, suggesting that some individuals convert most enterodiol to enterolactone, while others convert relatively little (1). Individual differences in the metabolism of lignans, likely due to differing composition and activities of gut microbes, can influence the biological activities and health effects of these compounds (7). Several other factors, including antibiotic use, age, BMI, and smoking, may also help explain the variation of circulating enterolignan concentrations among individuals (7); these and other potential confounding factors should be controlled for in observational studies.

Biological Activities

Estrogenic and anti-estrogenic activities

Estrogens are signaling molecules (i.e., hormones) that exert their effects by binding to estrogen receptors within cells (**Figure 3**). The estrogen-receptor complex interacts with DNA to change the expression of estrogen-responsive genes. Estrogen receptors are present in numerous tissues other than those associated with reproduction, including bone, liver, heart, and brain (8). Although phytoestrogens can also bind to estrogen receptors, their estrogenic activity is much weaker than endogenous estrogens, and they may actually block or antagonize the effects of estrogen in some tissues (9). Scientists are interested in the tissue-selective activities of phytoestrogens because anti-estrogenic effects in reproductive tissue could help reduce the risk of hormone-associated cancers (breast, uterine, ovarian, and prostate cancers), while estrogenic effects in bone could help maintain bone mineral density. The enterolignans, enterodiol and enterolactone, are known to have weak estrogenic activity. At present, the extent to which enterolignans exert weak estrogenic and/or anti-estrogenic effects in humans is not well understood.

Figure 3. Chemical Structures of Some Endogenous Mammalian Estrogens



Estrogen receptor-independent activities

Enterolignans have biological activities that are unrelated to their interactions with estrogen receptors. By altering the activity of enzymes involved in estrogen metabolism, lignans may change the biological activity of endogenous estrogens (10). Lignans have also been shown to display antioxidant activity in laboratory studies (11), although the significance in humans is not entirely clear since lignans are rapidly and extensively metabolized. For example, a cross-sectional study found that a biomarker of oxidative damage was inversely associated with serum enterolactone concentrations in men (12), but this association could be due to enterolactone and/or other antioxidants present in lignan-rich foods. Moreover, enterolignans may have anti-inflammatory properties, as well as anti-proliferative and anticancer activities that are independent of estrogen signaling (13-15).

Disease Prevention

Cardiovascular disease

Diets rich in foods containing plant lignans (whole grains, nuts and seeds, legumes, and fruit and vegetables) have been consistently associated with reductions in risk of cardiovascular disease. However, it is likely that numerous nutrients and phytochemicals found in these foods contribute to their cardioprotection.

Higher dietary intakes of two lignans, matairesinol and secoisolariciresinol, were not linked to total cardiovascular disease in 16,162 middle-aged and older women participating in the Dutch PROSPECT European Prospective study Into Cancer and nutrition (EPIC) study (16). A large prospective cohort study conducted within Spain's PREDIMED trial — a trial evaluating the effects of a Mediterranean diet on cardiovascular disease outcomes — followed 7,172 older adults at high risk of cardiovascular disease for a mean of 4.3 years (17). In this study, the highest quintile of dietary lignan intake (mean intake, 0.94 mg/day), measured by a food frequency questionnaire at baseline, was associated with a 49% lower risk of incident cardiovascular disease compared to the lowest quintile (mean intake, 0.44 mg/day of lignans). The primary dietary source of lignans in this cohort was virgin olive oil (17), which itself is known to be cardioprotective.

Coronary heart disease

In a prospective, nested case-control study in 334 middle-aged Finnish men, followed for an average of 7.7 years, higher serum enterolactone concentrations (a marker of plant lignan intake) were associated with a lower risk of acute coronary events (18). A prospective cohort study of 1,889 Finnish men followed for an average of 12 years, found those with the highest serum enterolactone concentrations were significantly less likely to die from coronary heart disease (CHD) or cardiovascular disease than those with the lowest concentrations (19). However, a study in male smokers did not find strong support for an association between serum enterolactone concentration and CHD (20). Additionally, a nested case-control study in men and women residing in the Netherlands did not find association between plasma concentrations of enterolactone or enterodiol and nonfatal myocardial infarction (236 cases and 283 controls), although the study population was young (ages 20-59 at baseline) and followed for only a mean of 4.5 years (21). A 2017 meta-analysis of three of these studies found no association between blood enterolactone concentration and non-fatal myocardial infarction (22). Moreover, dietary lignan intake was not linked to coronary cardiovascular disease in women participating in the Dutch PROSPECT EPIC study (16).

Clinical trials of lignan supplementation would be needed to determine the effects of lignans on coronary heart disease.

Cardiovascular risk factors

Blood lipids. Flaxseeds are among the richest sources of plant lignans in the human diet, but they are also good sources of other nutrients and phytochemicals with cardioprotective effects, such as omega-3 fatty acids (i.e., α-linolenic acid) and fiber. Supplementation trials have generally used ground or milled flaxseed (i.e., flax meal), which has a higher bioavailability of enterolignans compared to whole flaxseed (23). Five small clinical trials found that adding 30 to 50 g/day of flaxseed to the usual diet for 4 to 12 weeks resulted in modest 8%-20% decreases in low-density lipoprotein (LDL-cholesterol concentration (24-28), but four other trials did not observe significant reductions in LDL-cholesterol after adding 30 to 40 g/day of flaxseed to the diet (29-32). A double-blind, randomized controlled trial in adults, ages 44 to 75 years, found that supplementation with 40 g/day of flaxseed led to significant reductions in LDL-cholesterol after five weeks, but the cholesterol reductions were not statistically significant following 10 weeks' supplementation (33). Additionally, a one-year clinical trial in postmenopausal women reported that supplementation with 40 g/day of flaxseed did not lower LDL-cholesterol compared to a placebo containing wheat germ (34). Most of these trials were in healthy participants free of cardiovascular disease. In a randomized, double-blind, placebo-controlled trial in 84 patients with peripheral artery disease, 30 g/day of flaxseed for 12 months did not reduce total or LDL-cholesterol compared to placebo, although cholesterol reductions within the flaxseed-supplemented group were evident at 1 month and 6 months compared to baseline but not at 12 months (35).

Any effect of flaxseed supplementation on blood lipids might be attributed to flaxseed constituents other than lignans (i.e., protein, fiber, omega-3 fatty acids, phytochemicals). At least two trials have investigated the effect of supplementation with isolated flaxseed lignan. In a randomized, double-blind, placebo-controlled cross-over trial in 22 healthy postmenopausal women, six-week supplementation with 500 mg/day of secoisolariciresinol diglucoside — derived from flaxseed — had no effect on LDL-cholesterol concentration or other measured blood lipids despite significant increases in serum enterolactone concentration (36). Additionally, a randomized, double-blind, placebo-controlled cross-over trial in 68 patients with type 2 diabetes and mild hypercholesterolemia found no effect of 360 mg/day of secoisolariciresinol diglucoside for 12 weeks on concentration of blood cholesterol or other blood lipids (37).

Large-scale supplementation trials with isolated lignans would be needed to determine whether lignans have cholesterol-lowering effects.

Blood pressure. A 2016 meta-analysis pooled the results of 15 randomized controlled trials, some in healthy participants and some in participants with chronic disease (i.e., type 2 diabetes, metabolic syndrome, peripheral arterial disease) or risk factors of cardiovascular disease. Supplementation with flaxseed was linked to a 2.9 mm Hg reduction in systolic blood pressure and a 2.4 mm Hg reduction in diastolic blood pressure; these blood pressure reductions were greater in trials of longer duration (≥12 weeks vs. <12 weeks; 38). Additionally, data stratification by supplement type revealed a benefit of supplemental flaxseed powder but not of lignan extracts containing 360 to 600 mg/day of secoisolariciresinol diglucoside (38), suggesting the non-lignan constituents of flaxseed may be responsible for any blood pressure-lowering effects.

Hormone-associated cancers

Breast cancer

Overall, there is limited evidence that dietary intake of plant lignans is associated with breast cancer risk; studies on the association have reported conflicting results. Two prospective cohort studies examining plant lignan intake and breast cancer found no association (39, 40). A more recent prospective study reported no association between total lignan intake and breast cancer in premenopausal women (41). In another prospective analysis, the same group of authors found postmenopausal women in the highest quartile of dietary lignan intake had a 17% lower risk of breast cancer compared to women in the lowest quartile, but this protective association was only observed in women with estrogen-positive and progesterone-positive tumors (42). A prospective cohort study of 51,823 postmenopausal Swedish women, followed for an average of 8.3 years, found that women in the highest quartile of lignan intake (≥1,036 mg/day) had a 17% lower risk of invasive breast tumors compared to those in the lowest quartile (lignan intake <712 mg/day) (43). In this study, a strong inverse association of lignan intake and breast cancer risk was observed in women who had used postmenopausal hormones at some point in their life, but no association was evident in those who had never used such hormones (43). A 2009 meta-analysis did not find an overall association between dietary lignan intake and breast cancer, but when the analysis was limited to postmenopausal women, the authors reported a 15% reduction in risk of breast cancer with high lignan intake (44). A similar result was found in a subsequent meta-analysis that included 11 prospective cohort and 10 case-control studies: no association of lignan intake and breast cancer was observed in women overall, but data stratification by menopausal status revealed that the highest lignan intakes were associated with a 14% lower risk of breast cancer among postmenopausal women (13 studies; 45).

Several studies, mainly case-control studies, have examined the relationship between blood or urine concentrations of enterolactone and breast cancer, reporting conflicting results (46-48). Two meta-analyses did not find an association between blood concentrations of enterolactone and breast cancer (44, 45).

At present, it is not clear whether high intakes of plant lignans or high circulating levels of enterolignans offer significant protection against breast cancer. Randomized controlled trials of lignan supplementation would be needed to address this question.

Endometrial and ovarian cancers

Overall, there is limited evidence that dietary lignan intake or circulating enterolignan concentration (a marker of lignan intake) is associated with endometrial cancer or ovarian cancer.

In a case-control study of lignans and endometrial cancer, US women with the highest intakes of plant lignans had the lowest risk of endometrial cancer, but the reduction in risk was statistically significant in postmenopausal women only (49). However, two population-based, case-control studies, one conducted in the US (50) and one in Australia (51), found dietary lignan intake was not linked to endometrial cancer. Moreover, a prospective case-control study in three different countries (US, Sweden, and Italy) did not find an association between circulating enterolactone and endometrial cancer in premenopausal or in postmenopausal women (52). A large case-cohort study among Danish women, ages 50-64 years, also reported no association of plasma enterolactone concentration and endometrial cancer (53).

In an early case-control study among US women ages 40 to 85 years, those with the highest combined intakes of the lignans, secoisolariciresinol and matairesinol, had the lowest risk of ovarian cancer — intakes greater than 708 mg/day of these lignans were associated with a 57% lower risk of ovarian cancer compared with intakes less than 304 mg/day (54). A case-control study in Australia reported no association of total dietary lignans and risk of ovarian cancer but found a significant, inverse association of matairesinol and lariciresinol, individually, with ovarian cancer (51). However, two other studies, a population-based case-control study in the US (55) and a prospective cohort study in Sweden (56) found no relationship between dietary lignan intake and ovarian cancer.

Although some of these studies support the hypothesis that diets rich in plant foods may be helpful in decreasing the risk of hormone-associated cancers, they do not provide strong evidence that lignans in particular are protective against endometrial or ovarian cancer.

Prostate cancer

Several observational studies have examined the association between dietary lignan intake or circulating enterolignan concentration (a marker of lignan intake) and prostate cancer, with most reporting no association. A meta-analysis of three studies (two population-based, case-control studies and one nested case-control study) found lignan intake was not linked to prostate cancer risk (57). Moreover, a meta-analysis of nested case-control studies did not find circulating concentration of enterolactone (total of 2,828 cases and 5,593 controls pooled from five studies) or enterodiol (total of 1,002 cases and 1,197 controls pooled from two studies) to be associated with prostate cancer (58). Yet another meta-analysis found no association between dietary lignan intake (total lignans, or matairesinol or secoisolariciresinol, separately) or circulating enterolactone concentration and prostate cancer risk (59). While adherence to a plant-based diet may be linked to a lower risk of prostate cancer (60), evidence that dietary lignans are protective is lacking.

Osteoporosis

Research on the effects of dietary lignan intake on osteoporosis risk is very limited. In a prospective cohort study of 2,580 postmenopausal women and 4,973 men enrolled in the European Prospective Investigation into Cancer (EPIC) study, dietary intake of matairesinol and secoisolariciresinol was not associated with bone density, when assessed by ultrasound of the heel bone (61). In two much smaller observational studies, urinary enterolactone excretion was used as a marker of dietary lignan intake. One study of 75 postmenopausal Korean women, who were classified as osteoporotic, osteopenic, or normal on the basis of bone mineral density (BMD) measurements, found that urinary enterolactone excretion was positively associated with BMD of the lumbar spine and hip (62). However, a study of 50 postmenopausal Dutch women found that higher levels of urinary enterolactone excretion were associated with higher rates of bone loss (63).

In two separate placebo controlled trials, supplementation of postmenopausal women with 25 to 40 g/day of ground flaxseed for three to four months did not significantly alter biochemical markers of bone formation or bone resorption (loss) (31, 64). In a placebo-controlled trial that included a daily walking intervention in both groups of older adults, supplementation with a flaxseed lignan complex (containing 543 mg/day of secoisolariciresinol) for six months had no effect on bone mineral density measured by DXA (65).

More research is necessary to determine whether high dietary intakes of plant lignans can decrease the risk or severity of osteoporosis.

Type 2 diabetes mellitus

More than 10% of the US population has type 2 diabetes mellitus and another 35% has impaired glucose control (prediabetes) that places them at high risk of developing type 2 diabetes (66). A number of dietary polyphenols found in plant-based foods may affect glucose metabolism and thus aid in the prevention or management of the condition. A few observational studies have examined the association of lignan intake and incidence of diabetes. A prospective cohort study in 6,547 Iranian adults, followed for a mean of 3.0 years, reported an inverse association between dietary lignan intake (measured by food frequency questionnaire) and incidence of type 2 diabetes (67). In particular, this study found the highest versus lowest quartile of lignan intake (median of 9.1 mg/day vs. 1.6 mg/day) to be associated with a 40% lower risk of type 2 diabetes (67). However, no association between lignan intake (highest vs. lowest quintile of intake, median of 2.3 mg/day vs. 0.6 mg/day) and type 2 diabetes was reported in a prospective, case-cohort study conducted in Europe that included more than 15,000 adults (EPIC-InterAct; 68).

Studies that utilize biomarkers of lignan intake, such as urinary concentrations of enterodiol or enterolactone, provide a more accurate estimate of lignan intake compared to self-reported questionnaires (69). A prospective, nested case-control study of two cohorts of US women participating in the Nurses' Health Study (NHSI with mean age of 66 years and NHSII with mean age of 45 years) found lower concentrations of enterodiol and enterolactone in diabetic case subjects than in controls (70). Upon adjustment for potential confounders, only higher concentrations of urinary enterolactone were associated with a lower risk of developing type 2 diabetes, and this was driven by a significant association in the younger cohort of women (70). A nested case-control study within men and women participating in the Singapore Chinese Health Study (mean age, 59.8 years) reported no association between urinary enterodiol or enterolactone and type 2 diabetes (71).

Because higher lignan intakes may be a marker of a healthy diet in general, randomized controlled trials of lignan supplementation in healthy individuals would inform whether lignans affect glucose homeostasis and risk of developing type 2 diabetes. Interestingly, an eight-week, double-blind, placebo-controlled trial in hypercholesterolemic individuals found that a flaxseed lignan extract containing 600 mg/day of secoisolariciresinol diglucoside decreased fasting glucose concentrations compared to placebo, and the effect was stronger in those with higher baseline glucose concentrations (72). Supplementation with an extract containing 300 mg/day of secoisolariciresinol diglucoside had no effect on fasting glucose concentrations (72).

Mortality

A few studies have examined whether dietary lignan intake is related to all-cause and cause-specific mortality. The European Prospective Investigation into Cancer and Nutrition (EPIC)-Spain prospective cohort study investigated the relationship between lignan intake and all-cause mortality in 40,622 adults (ages 29-70 years) (73). After a mean follow-up of 13.6 years, dietary lignan intake was not associated with all-cause mortality (73). Additionally, dietary lignan intake was not linked to all-cause mortality in a much smaller study that followed 570 older Dutch men for 15 years (74). In this study, an inverse association was observed for intake of a specific lignan, matairesinol, with all-cause mortality and cardiovascular-related mortality, including death from coronary heart disease, although wine consumption modified these associations (74). However, an analysis of a 4.8-year trial that investigated the health effects of a Mediterranean diet in 7,172 older adults at high risk for cardiovascular disease (the PREDIMED trial in Spain) revealed that those in the highest quintile of lignan intake (mean of 0.94 mg/day) had a 40% lower risk of all-cause mortality compared to the lowest quintile (mean of 0.44 mg/day of lignans; 75). A 2017 meta-analysis found no association of lignan intake with all-cause mortality (3 studies mentioned above) or with mortality related to cardiovascular disease (2 studies; 76).

Other studies have assessed whether blood or urinary biomarkers of lignan intake are associated with mortality. In a prospective cohort study of 1,889 healthy, middle-aged Finnish men, followed for a mean of 12.2 years, the highest quartile of serum enterolactone concentration was associated with a 56% lower risk of coronary heart disease-related mortality and a 45% lower risk of cardiovascular disease-related mortality; no association of serum enterlactone and all-cause mortality was found in this study (19). However, serum enterolactone was not associated with coronary death in a case-cohort study in Finnish male smokers (20). In a national cross-sectional survey of US adults (NHANES 1999-2004), those in the highest tertile of urinary total enterolignan concentration had a lower risk of cardiovascular-related and all-cause mortality, and those with the highest urinary enterolactone concentrations had a significantly lower risk of all-cause mortality (77). These measures were not associated with mortality from cancer in this analysis, and urinary enterodiol concentration was not related to any of the mortality endpoints (77). A 2017 meta-analysis that combined results of these studies of lignan biomarkers found that enterolactone was inversely associated with both cardiovascular disease-related mortality and all-cause mortality (22). Most recently, a case-cohort study within the Danish Diet, Cancer and Health cohort found that higher pre-diagnostic plasma concentrations of enterolactone were linked to a lower risk of all-cause and diabetes-specific mortality among adults with type 2 diabetes (78).

Sources

Food sources

Lignans are present in a wide variety of plant foods, including seeds (flax, pumpkin, sunflower, poppy, sesame), whole grains (rye, oats, barley), bran (wheat, oat, rye), beans, fruit (particularly berries), vegetables, and beverages like tea, coffee, and wine (47, 79, 80). Secoisolariciresinol, matairesinol, pinoresinol, and lariciresinol contribute substantially to total dietary lignan intakes, although this varies with dietary pattern (80).

Flaxseed is by far the richest dietary source of plant lignans (81), and lignan bioavailability can be improved by crushing or milling flaxseed (23). Lignans are not associated with the oil fraction of foods, so flaxseed oils do not typically provide lignans unless ground flaxseed has been added to the oil. A variety of factors may affect the lignan content of plants, including geographic location, climate, maturity, and storage conditions. **Table 1** provides the total lignan (secoisolariciresinol, matairesinol, pinoresinol, and lariciresinol) content of selected lignan-rich foods (82). The Phenol-Explorer (version 3.6) database lists content of 25 different lignans in various foods.

Surveys have found median total lignan intake to be 0.98 mg/day in the Netherlands (83), 0.85 mg/day in Canada (84), and 0.76 mg/day in Spain (85). Plant lignans are the principal source of phytoestrogens in the diets of people who do not typically consume soy foods. The daily phytoestrogen intake of postmenopausal women in the US was estimated to be less than 1 mg/day, with 80% from lignans and 20% from isoflavones (86).

Table 1. Total Lignan Content of Selected Foods

Food	Serving	Total Lignans (mg)
Flaxseeds	1 oz	85.5
Sesame seeds	1 oz	11.2
Curly kale	½ cup, chopped	0.8
Broccoli	½ cup, chopped	0.6
Apricots	½ cup, sliced	0.4
Cabbage	½ cup, chopped	0.3
Brussels sprouts	½ cup, chopped	0.3
Strawberries	½ cup	0.2
Tofu	¼ block (4 oz)	0.2
Dark rye bread	1 slice	0.1

Supplements

Dietary supplements containing lignans derived from flaxseed are available in the US without a prescription (87); secoisolariciresinol is the primary lignan in such supplements (82).

Safety

Adverse effects

Lignan precursors in food are not known to have any serious adverse effects. Flaxseeds, which are rich in lignan precursors as well as dietary fiber, may increase stool frequency or cause diarrhea in doses of 45 to 50 g/day in adults (24, 88). One small, placebo-controlled study found that 50 mg/day of sesame lignans (1:1 mixture of sesamin and episesamin) for 28 days did not result in any serious adverse effects, although abdominal flatulence was associated with the sesame lignan supplementation (89). The safety of lignan supplements in pregnant or lactating women has not been established; therefore, lignan supplements should be avoided by women who are pregnant, breast-feeding, or trying to conceive.

Summary

- Plant sterols and plant stanols, known commonly as phytosterols, are plant-derived compounds that are structurally related to cholesterol. *(More information)*
- Early human diets were likely rich in phytosterols, providing as much as 1 g/day; however, the typical Western diet today is relatively low in phytosterols. *(More information)*
- Although phytosterols are present in the diet in amounts similar to cholesterol, they are poorly absorbed and blood concentrations tend to be low. After absorption into enterocytes, phytosterols are actively excreted back into the intestinal lumen by the ATP-binding cassette transporter, ABCG5/G8. *(More information)*
- Phytosterols interfere with the intestinal absorption of dietary cholesterol by displacing cholesterol from micelles; they also facilitate the excretion of biliary cholesterol in the feces. *(More information)*
- Numerous clinical trials have demonstrated that daily consumption of phytosterols from phytosterol-enriched foods can significantly lower serum low-density lipoprotein (LDL)-cholesterol. An average phytosterol intake of 2 g/day lowers serum LDL-cholesterol by 8%-10%. *(More information)*
- The effect of long-term use of foods enriched with phytosterols on cardiovascular risk is not known. *(More information)*
- The results of a few clinical trials suggested that phytosterol supplementation at relatively low doses can improve urinary tract symptoms related to benign prostatic hyperplasia, but further research is needed to confirm these findings. *(More information)*
- Good food sources of phytosterols include unrefined vegetable oils, whole grains, nuts, seeds, and legumes. *(More information)*
- Foods and beverages with added phytosterols are now available in many countries throughout the world, and some countries allow health claims on such commercial products. *(More information)*
- Consumption of phytosterol-enriched foods may have undesirable effects, such as a reduction in plasma carotenoid concentrations. *(More information)*

Introduction

Throughout much of human evolution, it is likely that large amounts of plant foods were consumed (1). In addition to being rich in fiber and plant protein, the diets of our ancestors were also rich in phytosterols — plant-derived compounds that are structurally very similar to cholesterol (**Figure 1**). There is increasing evidence to suggest that the reintroduction of plant foods providing phytosterols into the modern diet could improve serum lipid (cholesterol) profiles and help reduce the risk of cardiovascular disease (1).

Cholesterol in human blood and tissues is derived from the diet, as well as from endogenous cholesterol synthesis. In contrast, all phytosterols in human blood and tissues are derived from the diet because humans cannot synthesize phytosterols (2). While cholesterol is the predominant sterol in animals, including humans, a variety of sterols are found in plants (3). Nutritionists recognize two classes of phytosterols:

(1) **Plant sterols** have a double bond in the sterol ring. The most abundant sterols in plants and the human diet are β-sitosterol, campesterol, and stigmasterol (**Figure 2**).

(2) **Plant stanols** lack a double bond in the sterol ring. Stanols, especially sitostanol and campestanol, comprise only about 10% of total dietary phytosterols (**Figure 3**).

Definitions

Phytosterols: a collective term for plant-derived sterols and stanols.

Plant sterols or stanols: terms generally applied to plant-derived sterols or stanols; these phytochemicals are added to food or supplements.

Plant sterol or stanol esters: plant sterols or stanols that have been esterified by creating an ester bond between a fatty acid and the sterol or stanol. Esterification occurs in intestinal cells and is also an industrial process. Esterification makes plant sterols and stanols more fat-soluble so they are easily incorporated into fat-containing foods, including margarines and salad dressings. In this article, the weights of plant sterol and stanol esters are expressed as the equivalent weights of free (unesterified) sterols and stanols.

Metabolism and Bioavailability

Absorption and metabolism of dietary cholesterol

Dietary cholesterol must be incorporated into mixed micelles in order to be absorbed by the cells that line the intestine (enterocytes) (4). Mixed micelles are mixtures of bile salts, lipids, and sterols formed in the small intestine after a fat-containing meal is consumed. Transport across the apical membrane of enterocytes is mediated by intestinal cholesterol transporter, Niemann Pick C1-Like 1 (NPC1L1), which is also involved in the uptake of phytosterols (5). Inside the enterocyte, cholesterol is esterified in a reaction catalyzed by intestinal acyl-coenzyme A (CoA) cholesterol acyltransferases (ACATs; also present in the liver) and incorporated into triglyceride-rich lipoproteins known as chylomicrons, which are secreted into the intestinal lymphatics. The thoracic lymphatic duct then collects most of the lymph before draining into the systemic blood circulation (6). As circulating chylomicrons become depleted of triglycerides, they become chylomicron remnants, which are taken up by the liver. In the liver, cholesterol from chylomicron remnants may be repackaged into other lipoproteins for transport throughout the circulation or, alternatively, secreted into bile, which is released into the small intestine.

Absorption and metabolism of dietary phytosterols

Although varied diets typically contain similar amounts of phytosterols and cholesterol, serum phytosterol concentrations are usually several hundred times lower than serum cholesterol concentrations in humans (7). Less than 5% of dietary plant sterols and less than 0.5% of dietary plant stanols are systemically absorbed, in contrast to about 50%-60% of dietary cholesterol (8, 9). Like cholesterol, phytosterols must be incorporated into mixed micelles before they are taken up by enterocytes. Once inside the enterocyte, systemic absorption of phytosterols is inhibited by the activity of an efflux transporter, consisting of a pair of ATP-binding cassette (ABC) proteins known as ABCG5 and ABCG8. ABCG5 and ABCG8 each form one half of a transporter that secretes phytosterols and unesterified cholesterol from the enterocyte into the intestinal lumen. Phytosterols are secreted back into the intestine by ABCG5/G8 transporters at a much greater rate than cholesterol, resulting in much lower intestinal absorption of dietary phytosterols than cholesterol (10).

Within the enterocyte, phytosterols are not as readily esterified as cholesterol, so they are incorporated into chylomicrons at much lower concentrations. Those phytosterols that are incorporated into chylomicrons enter the circulation and are taken up by the liver. Once inside the liver, phytosterols are rapidly secreted into bile by hepatic ABCG5/G8 transporters. Although cholesterol is also secreted into bile, the rate of phytosterol secretion into bile is much greater than cholesterol secretion (11). Thus, the low serum concentrations of phytosterols relative to cholesterol can be explained by decreased intestinal absorption and increased excretion of phytosterols into bile.

Biological Activities

Effects on cholesterol absorption and excretion

It is well established that high intakes of plant sterols or stanols can lower serum total and low-density lipoprotein (LDL)-cholesterol concentrations in humans (see Cardiovascular disease). Different mechanisms appear to underlie the cholesterol-lowering effect of phytosterols (reviewed in 12). In the intestinal lumen, phytosterols displace cholesterol from mixed micelles and reduce cholesterol absorption (13). It is also suggested that phytosterols might interfere with the esterification and incorporation of cholesterol into chylomicrons inside the enterocytes (12). In a placebo-controlled, cross-over trial, the consumption of moderate (0.46 g/day) and high (2.1 g/day) phytosterol-enriched beverages reduced cholesterol absorption by about 10% and 25%, respectively (14). Moderate and high phytosterol intakes also significantly increased the excretion of biliary and dietary cholesterol in the feces by 36% and 74%, respectively (14). Although the mechanisms are currently not clear, phytosterols might facilitate cholesterol efflux from peripheral tissues and macrophages lining vessel walls. Cholesterol is then transported to the liver and incorporated into bile stored in the gallbladder. While plant sterols may promote the hepatobiliary secretion of cholesterol into the intestinal lumen, they are also hypothesized to facilitate the disposal of cholesterol via a nonbiliary route called transintestinal cholesterol efflux (TICE) (12).

Effects on cholesterol metabolism

A decrease in intestinal-derived cholesterol entering the circulation as chylomicrons triggers the endogenous production of cholesterol in order to maintain cholesterol homeostasis (14). Cell surface LDL-receptor expression is also up-regulated to enhance a receptor-mediated uptake of circulating LDL-cholesterol into cells (15). This process results in an increased clearance of circulating LDL from the blood. Within the cells, LDL particles are dismantled in lysosomes and cholesterol becomes available for metabolic needs. Through inhibiting the sterol regulatory element-binding protein (SREBP) pathway, LDL and LDL-derived cholesterol then suppress the transcription of the genes coding for 3-hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase and other enzymes involved in the synthesis of cholesterol and of the LDL-receptor (16). The net result is the maintenance of cellular cholesterol homeostasis within tissues (especially in the liver) and a reduction in serum LDL-cholesterol concentration.

(especially in the liver) and a reduction in serum LDL cholesterol concentration.

Of note, some individuals with low intestinal cholesterol absorption efficiency (17) and/or high basal cholesterol synthesis rate (18) have been found to be poorly responsive to phytosterol therapy (reviewed in 19).

Other biological activities

Experiments in cell culture and animal models have suggested that phytosterols might have biological activities unrelated to cholesterol lowering. However, their significance in humans is not yet known.

Alterations in cell membrane properties

Cholesterol is an important structural component of mammalian cell membranes (20). Displacement of cholesterol with phytosterols has been found to alter the physical properties of cell membranes *in vitro* (21), which could potentially affect signal transduction or membrane-bound enzyme activity (22, 23). Limited evidence from an animal model of hemorrhagic stroke suggested that very high intakes of phytosterols could displace cholesterol in red blood cell membranes, resulting in decreased deformability and potentially increased fragility (24, 25). However, daily phytosterol supplementation (1 g/1,000 kcal) for four weeks did not alter red blood cell fragility in humans (26).

Alterations in testosterone metabolism

Limited evidence from animal studies suggests that very high phytosterol intake could alter testosterone metabolism by inhibiting 5-α-reductase, a membrane-bound enzyme that converts testosterone to dihydrotestosterone, a more potent metabolite (27, 28). It is not known whether phytosterol consumption alters testosterone metabolism in humans. No significant changes in free or total serum testosterone concentrations were observed in men who consumed 1.6 g/day of plant sterol esters for one year (29).

Anticancer effects

Phytosterols have been found to inhibit proliferation, induce apoptosis, and reduce invasiveness of cancer cells in culture (reviewed in 30). There is currently little evidence to suggest that phytosterol consumption could substantially contribute to lower the risk of cancer in humans (see Cancer).

Anti-inflammatory effects

Limited data from cell culture and animal studies suggest that phytosterols may attenuate the inflammatory activity of immune cells, including macrophages and neutrophils (31, 32). The result of a recent meta-analysis of 20 randomized controlled trials found that reductions in total cholesterol and LDL-cholesterol concentrations with phytosterol-enriched foods were not associated with changes in plasma concentration of C-reactive protein (CRP), a surrogate marker of chronic low-grade inflammation (33).

Disease Prevention

Cardiovascular disease

Typical diets across different populations have been estimated to provide 150 to 450 mg/day of naturally occurring phytosterols. Nevertheless, the consumption of vegetarian diets and of food products enriched with phytosterols can help achieve much greater intakes of phytosterols (see Food sources). Relatively few studies have considered the effects of naturally occurring dietary phytosterol intakes on serum LDL-cholesterol concentrations, while an abundance of studies have examined the lipid-lowering effect of phytosterol-enriched foods.

Foods enriched with plant sterols or stanols

Lipid-lowering effect: Elevated LDL-cholesterol concentration is a well-established risk factor in the development of atherosclerosis and coronary heart disease (34, 35). Numerous clinical trials have found that daily consumption of foods enriched with free or esterified forms of plant sterols or stanols lowers concentrations of serum total and LDL-cholesterol (36-40). This wealth of evidence has been summarized in several meta-analyses combining the results of randomized controlled trials (41-46). A dose-dependent relationship was reported between total phytosterol intake levels (from less than 1 g/day to 4 g/day) and LDL-cholesterol reduction in a recent meta-analysis of 124 human studies (47). When analyzed separately, plant sterols and stanols showed similar dose-response effects on LDL-cholesterol concentrations for average doses ranging from 0.6 g/day to 3.3 g/day. Average doses of phytosterols between 0.6 and 1.1 g/day were found to significantly lower LDL-cholesterol concentrations by at least 5%, while an average intake of 3.3 g/day resulted in reductions of about 12.4% (47).

Another meta-analysis that analyzed the results of 59 randomized controlled trials suggested that reductions in LDL-cholesterol were greater in those with higher baseline concentrations of LDL-cholesterol (41). Interestingly, a recent meta-analysis of 15 randomized controlled trials investigating the effects of phytosterol-enriched food intake (1.8 to 6 g/day of phytosterols) in patients treated with statins (drugs that inhibit endogenous cholesterol synthesis) found that co-administration of phytosterols and statins significantly reduced total cholesterol and LDL-cholesterol concentrations compared to statin therapy alone (48). The concentrations of HDL-cholesterol and triglycerides were unaffected by the combination of phytosterols and statins compared to statin alone. In subgroup analyses, the effect of combining phytosterols and statins on blood lipid profile was not found to be significantly influenced by lipid baseline values, phytosterol dosage, or study duration (48).

Effect on vascular health: Impairment of vascular endothelial function is considered to be an early step in the development of atherosclerosis and cardiovascular disease (49). A recent 12-week randomized, double-blind, placebo-controlled study in 240 subjects with hypercholesterolemia (serum cholesterol ≥5 mmol/L [≥193 mg/dL]) found no effect of consuming 3 g/day of phytosterols added to low-fat spread on brachial artery flow-mediated dilation (FMD), a surrogate marker of endothelial health (50). Assessment of arterial stiffness — using measures of aortic pulse wave velocity (PWV) and augmentation index (AI) — and blood pressure also showed no difference between supplemented and placebo groups, despite a significant 6.7% reduction in total and LDL-cholesterol. Other trials in individuals with hypercholesterolemia (51, 52) and type 1 diabetes mellitus (53) also failed to find an effect of phytosterol-enriched spread consumption on brachial artery diameter, FMD, and/or arterial stiffness. Nonetheless, the results of a randomized controlled trial in 92 individuals of whom 72% had serum cholesterol ≥5 mmol/L suggested beneficial effects of plant stanol-enriched spread consumption (corresponding to 3 g/day of stanols for six months) on arterial stiffness and endothelial function, as assessed by cardio-ankle vascular index (CAVI) and reactive hyperemia index (RHI) measures, respectively (54). Finally, a 21-month randomized controlled trial used retinal photography to examine the effect of phytosterol-enriched margarine consumption on retinal microcirculation in 43 statin-treated subjects (55). Reductions in LDL-cholesterol concentration by 9.7% and 11.2% with plant sterols (2.5 g/day) and plant stanols (2.5 g/day), respectively, were not accompanied by significant changes in the diameter of retinal arterioles and venules, a proxy measure to assess microvascular health (55). At present, whether phytosterols can improve vascular health in individuals with endothelial dysfunction is unclear. The lack of an effect of phytosterols in most of the abovementioned trials may be due to the inclusion of apparently healthy participants who may have normal endothelial function (50).

Effect on the risk of coronary heart disease: Elevated LDL-cholesterol is an established risk factor for coronary heart disease (CHD) (56). The pooled analysis of 27 randomized controlled trials of statin drug therapy found a 24% decrease in the risk of major coronary events and a 12% decrease in vascular mortality per 1 millimol/L (1 mM) reduction in LDL-cholesterol concentration, irrespective of gender and level of cardiovascular risk (57). Yet, at present, the effect of long-term use of foods enriched with plant sterols or stanols on CHD risk is not known.

The addition of plant sterol- or stanol-enriched foods to a heart-healthy diet that is low in saturated fat and rich in fruit and vegetables, whole grains, and fiber offers the potential for additive effects in CHD risk reduction. For example, following a diet that substituted monounsaturated and polyunsaturated fats for saturated fat resulted in a 9% reduction in serum LDL-cholesterol after 30 days, but the addition of 1.7 g/day of plant sterols to the same diet resulted in a 24% reduction (58). In addition, one-month adherence to a diet providing a portfolio of cholesterol-lowering foods, including plant sterols (1 g/1,000 kcal), soy protein, almonds, and viscous fibers, lowered serum LDL-cholesterol concentrations by an average of 30% — a decrease that was not significantly different from that induced by statin therapy (59).

The National Cholesterol Education Program (NCEP) Adult Treatment Panel III included the use of plant sterol or stanol esters (2 g/day) as a component of maximal dietary therapy for elevated LDL-cholesterol (60). The 2013 report of the American College of Cardiology (ACC) task force advised clinicians to consider the use of phytosterol-enriched foods as dietary adjuncts for high-risk patients with insufficient LDL-cholesterol response to statin therapy (61). However, stepping back from a general recommendation, the ACC and American Heart Association (AHA) did not include phytosterols in their 2013 report on lifestyle management guidelines to reduce cardiovascular risk (62). Likewise, the 2015-2020 Dietary Guidelines for Americans — issued jointly by the US Department of Health and Human Services and the US Department of Agriculture — does not mention phytosterols in the composition of healthy eating patterns (63).

The US Food and Drug Administration (FDA) has authorized the use of health claims on food labels indicating that regular consumption of foods enriched with plant sterol or stanol esters, as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease (see Foods enriched with plant sterols and plant stanols) (61, 64). In the EU, disease risk reduction claims for phytosterols are restricted to certain fortified food products and include a number of mandatory statements such as the fact that these products are not intended for people who do not need to control their blood cholesterol level (65).

Dietary phytosterols

Clinical trials finding daily consumption of foods enriched with plant sterols or stanols can significantly lower LDL-cholesterol concentrations do not account for naturally occurring phytosterols in the diet (66). Relatively few studies have considered the effects of dietary phytosterol intakes on serum LDL-cholesterol concentrations. Limited evidence, primarily from cross-sectional studies, suggests that dietary phytosterols may play an important role in decreasing cholesterol absorption. A cross-sectional study in the UK found that dietary phytosterol intakes were inversely related to serum total and LDL-cholesterol concentrations even after adjusting for saturated fat and fiber intake (67). Similarly, an analysis in a Swedish population found that dietary intake of phytosterols was inversely associated with total cholesterol in both men and women and with LDL-cholesterol in women (68). Dietary phytosterol intakes were also found to be inversely associated with LDL-cholesterol concentrations in another cross-sectional study in healthy Spanish participants (69). In single-meal tests, removal of 150 mg of phytosterols from corn oil increased cholesterol absorption by 38% (70), and removal of 328 mg of phytosterols from wheat germ increased cholesterol absorption by 43% (71). Although these findings suggest that moderate intakes of phytosterols could have an important impact on cardiovascular health, the intake of phytosterols (83 to 966 mg/day) from natural sources was not found to be associated with reduced risks of CHD, myocardial infarction, or total cardiovascular disease during the 12.2-year follow-up of 35,597 participants of the European Prospective Investigation into Cancer and Nutrition-The Netherlands (EPIC-NL) (72).

Cancer

Limited data from animal studies suggest that very high intakes of phytosterols, particularly sitosterol, may inhibit the growth of breast and prostate cancer (reviewed in 73). Only a few observational studies have examined associations between dietary phytosterol intakes and cancer risk in humans (30). A series of case-control studies in Uruguay found that dietary phytosterol intakes were lower in people diagnosed with stomach, lung, or breast cancer than in cancer-free control groups (74-76). Case-control studies in the US found that women diagnosed with breast or endometrial (uterine) cancer had lower dietary phytosterol intakes than women who did not have cancer (77, 78). In contrast, another case-control study in the US found that men diagnosed with prostate cancer had higher dietary campesterol intakes than cancer-free men, but total phytosterol consumption was not associated with prostate cancer risk (79). Although higher intakes of plant foods containing phytosterols may be associated with lower cancer risk, it is not clear whether potential anticancer health benefits can be attributed to phytosterols or to other compounds in plant foods (e.g., other phytochemicals, vitamins, minerals, and fiber).

Disease Treatment

Benign prostatic hyperplasia

Benign prostatic hyperplasia (BPH) is the term used to describe a noncancerous enlargement of the prostate. The enlarged prostate may exert pressure on the urethra, resulting in difficulty urinating. Plant extracts that provide a mixture of phytosterols (marketed as β-sitosterol) are often included in herbal therapies for urinary symptoms related to BPH. However, relatively few controlled studies have examined the efficacy of phytosterol supplements in men with symptomatic BPH. In a six-month study of 200 men with symptomatic BPH, 60 mg/day of a β-sitosterol preparation improved symptom scores, increased peak urinary flow, and decreased post-void residual urine volume compared to placebo (80). A follow-up study reported that these improvements were maintained for up to 18 months in the 38 participants who continued β-sitosterol treatment (81). Similarly, in a six-month study of 177 men with symptomatic BPH, 130 mg/day of a different β-sitosterol preparation improved urinary symptom scores, increased peak urinary flow, and decreased post-void residual urine volume compared to placebo (82). A systematic review that combined the results of these and two other controlled clinical trials found that β-sitosterol extracts increased peak urinary flow by an average of 3.9 mL/second and decreased post-void residual volume by an average of 29 mL (83). Although the results of a few clinical trials suggest that relatively low doses of phytosterols can improve lower urinary tract symptoms related to BPH, further research is needed to confirm these findings (84).

Sources

Food

Unlike the typical diet in most developed countries today, the diets of our ancestors were rich in phytosterols, likely providing as much as 1 g/day (1). Present-day dietary phytosterol intakes have been estimated to vary from 150 to 450 mg/day in different populations (85). Vegetarians, particularly vegans, generally have the highest intakes of dietary phytosterols (86). Phytosterols are found in all plant foods, but the highest concentrations are found in unrefined plant oils, including vegetable, nut, and olive oils (3). Nuts, seeds, whole grains, and legumes are also good dietary sources of phytosterols (4). The phytosterol content of selected foods are presented in **Table 1**. For information on the nutrient content of specific foods, search the USDA food composition database.

Table 1. Total Phytosterol Content of Selected Foods

Food	Serving	Phytosterols* (mg)
Soybeans, mature seeds, raw	½ cup	149
Peas, green, mature seeds, raw	½ cup	133
Sesame oil	1 tablespoon (14 g)	118
Kidney beans, mature seeds, raw	½ cup	117
Pistachio nuts	1 ounce (49 kernels)	61
Safflower oil	1 tablespoon (14 g)	60
Lentils, pink or red, mature seeds, raw	½ cup	54
Cashew nuts	1 ounce	45
Soybeans, green, cooked, boiled	½ cup	45
Cottonseed oil	1 tablespoon (14 g)	44
Orange, raw	1 fruit	34
Macadamia nuts	1 ounce (10-12 kernels)	33
Almonds, blanched	1 ounce	32
Olive oil	1 tablespoon (14 g)	30
Banana, raw	1 large	24
Brussels sprouts, raw	1 cup	21

*In the USDA food composition database, the values of phytosterol content of foods are likely to be underestimates since they account only for major sterols (sitosterol, campesterol, and stigmasterol). In addition, the values correspond to the amounts of free and esterified phytosterols in foods, because phytosterol glycosides are not quantified by the current method unless glycosides (sugars) are removed before quantification (87).

Food enriched with plant sterols and plant stanols

Clinical trials that demonstrated a cholesterol-lowering effect have primarily used plant sterol or stanol esters solubilized in fat-containing foods, such as margarine or mayonnaise (44). Additional studies indicate that low-fat or even nonfat foods can effectively deliver plant sterols or stanols if they are adequately solubilized (37, 66). Plant sterols or stanols added to low-fat yogurt (88-91), low-fat milk (92-94), low-fat cheese (95), dark chocolate (96), and orange juice (97, 98) have been reported to lower LDL-cholesterol in randomized controlled trials. A variety of foods containing added plant sterols or stanols, including margarines, mayonnaises, vegetable oils, salad dressings, yogurt, milk, soy milk, orange juice, snack bars, and meats, are available in the US, Europe, Asia, Australia, and New Zealand (37). A 2008 meta-analysis found that phytosterols added to fat spreads, mayonnaise, salad dressings, milk, or yogurt more effectively reduced LDL-cholesterol concentrations compared to phytosterols incorporated into chocolate, orange juice, cheese, meats, and cereal bars (41). In most clinical trials, dividing the daily dose of phytosterols among two or three meals appeared to effectively lower LDL-cholesterol (41). Nevertheless, consumption of the daily dose of plant sterols or stanols with a single meal has also been found to lower LDL-cholesterol in a few clinical trials (89-91, 99, 100).

In the US, FDA-authorized health claims on food labels specify that the daily dietary intake of plant sterol (≥1.3 g/day) or stanol esters (≥3.4 g/day) that has been associated with a reduced risk of heart disease should be consumed in two servings eaten at different times of the day with other foods, as part of a diet low in saturated fat and cholesterol (61, 64). In the EU, food labels must indicate that the beneficial effect of phytosterols is obtained with a daily intake of 1.5 to 3 g of plant sterols/stanols in order to use the following European Food Safety Authority (EFSA)-approved statement: "Plant sterol and stanol esters have been shown to lower blood cholesterol. High cholesterol is a risk factor in the development of coronary heart disease" (65).

Supplements

Available without a prescription in the US, β-sitosterol supplements typically contain a mixture of β-sitosterol with other phytosterols and/or with substances like pumpkin seed oil and saw palmetto extract (101). Doses of 60 to 130 mg/day of β-sitosterol have been found to alleviate the symptoms of benign prostatic hyperplasia in a few clinical trials (see Benign prostatic hyperplasia). Phytosterol and phytostanol supplements should be taken with a meal that contains fat.

Safety

In the US, plant sterols and stanols added to a variety of food products are generally recognized as safe (GRAS) by the FDA (102). Additionally, the Scientific Committee on Foods of the EU concluded that plant sterols and stanols added to various food products are safe for human use (103). However, the Committee recommended that intakes of plant sterols and stanols from food products should not exceed 3 g/day because there is no evidence of health benefits at higher intakes and there might be undesirable effects at high intakes (65).

Adverse effects

Few adverse effects have been associated with regular consumption of plant sterols or stanols for up to one year. People who consumed a plant sterol-enriched spread providing 1.6 g/day did not report any more adverse effects than those consuming a control spread for up to one year (29), and people consuming a plant stanol-enriched spread providing 1.8 to 2.6 g/day for one year did not report any adverse effects (104). Consumption of up to 8.6 g/day of phytosterols in margarine for three to four weeks was well tolerated by healthy men and women and did not adversely affect intestinal bacteria or female hormone levels (105). Although phytosterols are usually well tolerated, nausea, indigestion, diarrhea, and constipation have occasionally been reported (106).

Sitosterolemia

Sitosterolemia, also known as phytosterolemia, is a very rare hereditary disease that results from inheriting a mutation in both copies of the *ABCG5* or *ABCG8* gene (107). Individuals who are homozygous for a mutation in either transporter protein have dramatically elevated serum phytosterol concentrations due to increased intestinal absorption and decreased biliary excretion of phytosterols. Although serum cholesterol concentrations may be normal or only mildly elevated, individuals with sitosterolemia are at high risk for premature atherosclerosis. Other clinical symptoms include tuberous and tendon xanthomas (i.e., cutaneous lipid depositions), hematological abnormalities, and sometimes joint pain and arthritis.

People with sitosterolemia should avoid foods or supplements with added plant sterols (37). Two studies have examined the effect of plant sterol consumption in heterozygous carriers of sitosterolemia, a more common condition. Consumption of 3 g/day of plant sterols for four weeks by two heterozygous carriers (108) and consumption of 2.2 g/day of plant sterols for 6 to 12 weeks by 12 heterozygous carriers did not result in abnormally elevated serum phytosterols (109). Because atherosclerosis has been reported in subjects with sitosterolemia, phytosterols have been attributed atherogenic effects. However, no relationship between serum concentrations of sitosterol and campesterol and risk of cardiovascular disease has been identified in a recent meta-analysis of 17 observational studies in 11,182 participants (110).

Pregnancy and lactation

Phytosterol-enriched foods and supplements are not recommended for pregnant or breast-feeding women because their safety has not been studied (106). At present, there is no evidence that high dietary intakes of naturally occurring phytosterols, such as those consumed by vegetarian women, adversely affects pregnancy or lactation.

Drug interactions

Statins

There is some evidence showing that statin administration initially reduces plant sterol concentrations in blood. This might be attributed to the reduction of circulating LDL, the major transport lipoprotein of plant sterols, due to enhanced hepatic uptake of LDL. However, statin therapy appears to increase the absorption of plant sterols that can be then transported by the remaining LDL particles (111). Further, the LDL-cholesterol-lowering effect of plant sterols or stanols may be additive to that of statins. The result of a recent meta-analysis of controlled clinical trials suggested that consumption of 2 to 3 g/day of plant sterols or stanols by individuals on statin therapy may lower both total cholesterol and LDL-cholesterol by an additional 0.30 mmol/L (11.6 mg/dL), compared to statin alone (48).

Ezetimibe

Ezetimibe (marketed as Zetia) is another cholesterol-lowering drug that may interfere with the intestinal absorption of phytosterols, thus significantly reducing phytosterol concentration in blood (112).

Nutrient interactions

Fat-soluble vitamins (vitamins A, D, E, and K)

Because plant sterols and stanols decrease cholesterol absorption and serum LDL-cholesterol concentrations, their effects on fat-soluble vitamin status have also been studied in clinical trials. Plasma vitamin A (retinol) concentrations were not affected by consumption of plant sterol esters or plant stanol esters for up to one year (29, 44). Although the majority of studies found no changes in plasma vitamin D (25-hydroxyvitamin D_3) concentrations, one placebo-controlled study in individuals consuming 1.6 g/day of sterol esters for one year observed a small (7%) but statistically significant decrease in plasma 25-hydroxyvitamin D_3 concentrations (29). There is little evidence that plant sterol or stanol consumption adversely affects vitamin K status. Consumption of 1.6 g/day of sterol esters for six months was associated with a nonsignificant, 14% decrease in plasma vitamin K_1 (phylloquinone) concentrations, and the level of carboxylated osteocalcin, a functional indicator of vitamin K status, was unchanged (29). Other studies of shorter duration also found no change in plasma concentrations of phylloquinone (113, 114) or vitamin K-dependent clotting factors with the consumption of plant sterol and stanol esters (115). Consumption of phytosterol-enriched foods has been found to decrease plasma vitamin E (α-tocopherol) concentration in a number of studies (44, 114). However, those decreases generally do not persist when plasma α-tocopherol concentrations are standardized to LDL-cholesterol concentrations, suggesting that observed reductions in plasma α-tocopherol are due in part to reductions in its lipoprotein carrier, LDL.

A recent meta-analysis of intervention studies found no adverse effects of phytosterol-enriched food consumption (average dose of 2.5 g/day) on fat-soluble vitamin status in well-nourished people (116).

Carotenoids

Dietary carotenoids are fat-soluble phytochemicals that circulate in lipoproteins. A recent meta-analysis of randomized controlled studies reported about 5 to 20% reductions in plasma hydrocarbon carotenoids after consumption of plant sterol- or stanol-enriched foods for one month to one year (116). Even when standardized to serum total cholesterol concentrations, decreases in α-carotene, β-carotene, and lycopene may persist, suggesting that phytosterols could inhibit the absorption of these carotenoids. Total cholesterol-standardized concentrations of xanthophyll carotenoids, zeaxanthin and β-cryptoxanthin, but not lutein, were also found to be significantly reduced by 5 to 15% with the consumption of phytosterol-enriched foods (116).

Although it is not clear whether reductions in plasma carotenoid concentrations confer any health risks (see the article on Carotenoids), a few studies showed that increasing intakes of carotenoid-rich fruit and vegetables would prevent phytosterol-induced decreases in plasma concentrations of carotenoids (117). In one randomized controlled study, advice to consume five daily servings of fruit and vegetables, including one serving of carotenoid-rich vegetables, was enough to maintain plasma carotenoid levels in people consuming 2.5 g/day of plant sterol or stanol esters (118).

Summary

- Resveratrol is a polyphenolic compound naturally found in peanuts, grapes, red wine, and some berries. *(More information)*
- When taken orally, resveratrol is well absorbed by humans, but its bioavailability is relatively low because it is rapidly metabolized and eliminated. *(More information)*
- In preclinical studies, resveratrol has been shown to possess numerous biological activities, which could possibly be applied to the prevention and/or treatment of cancer, cardiovascular disease, and neurodegenerative diseases. *(More information)*
- Although resveratrol can inhibit the growth of cancer cells in culture and in some animal models, it is not known whether resveratrol can prevent and/or help treat cancer in humans. *(More information)*
- The presence of resveratrol in red wine was initially thought to be responsible for red wine's beneficial cardiovascular effects. Two randomized, placebo-controlled trials reported that one-year consumption of a grape supplement containing 8 mg/day of resveratrol improved inflammatory and atherogenic status in subjects at risk for cardiovascular disease, as well as in patients with established coronary heart disease. Yet, there is currently no evidence that the content of resveratrol in red wine confers any additional risk reduction beyond that attributed to the alcohol content and to other wine polyphenols. *(More information)*
- Resveratrol administration has increased the lifespans of yeast, worms, fruit flies, fish, and mice fed a high-calorie diet, but it is not known whether resveratrol will have similar effects in humans. *(More information)*
- Experimental animal studies have suggested that resveratrol might be neuroprotective and be beneficial in the prevention and/or treatment of neurodegenerative diseases; however, clinical trials in healthy or cognitively impaired older people are currently very limited. *(More information)*
- In randomized controlled trials, short-term supplementation with resveratrol significantly improved glucose and lipid metabolic disorders in patients with type 2 diabetes. *(More information)*
- Long-term, high resveratrol intake might affect the pharmacokinetics of certain drugs (i.e., those metabolized by cytochrome P450 enzymes), potentially reducing their efficacy or increasing their toxicity. *(More information)*

Introduction

Resveratrol (3,4',5-trihydroxystilbene) belongs to a class of polyphenolic compounds called stilbenes (1). Certain plants produce resveratrol and other stilbenoids in response to stress, injury, fungal infection, or ultraviolet (UV) radiation (2). Resveratrol is a fat-soluble compound that occurs in both *trans* and *cis* molecular configurations (**Figure 1**). Both *cis*- and *trans*-resveratrol also occur as glucosides, i.e., bound to a glucose molecule. One major resveratrol derivative is resveratrol-3-O-β-glucoside, also called piceid (**Figure 1**) (3).

Since the early 1990s, when the presence of resveratrol in red wine was established (4), the scientific community has been exploring the effects of resveratrol on health. Specifically, it was postulated that resveratrol intake via moderate red wine consumption might help explain the fact that French people have a relatively low incidence of coronary heart disease (CHD) in spite of consuming foods high in saturated fat, a phenomenon dubbed the "French Paradox" (see Cardiovascular disease) (5). Since then, reports on the potential for resveratrol to prevent cancer, delay the development of cardiovascular and neurodegenerative diseases, improve glycemic control in type 2 diabetes, and extend lifespan in experimental models have continued to generate scientific interest (see Disease Prevention).

Metabolism and Bioavailability

Initial studies of the pharmacokinetics of *trans*-resveratrol in humans found only traces of the unmetabolized resveratrol in the plasma upon oral exposure of single *trans*-resveratrol doses of 5 to 25 mg. Indeed, *trans*-resveratrol appears to be well absorbed by humans when taken orally, but its bioavailability is relatively low due to its rapid metabolism and elimination (6). Once absorbed, resveratrol is rapidly metabolized by conjugation to glucuronic acid and/or sulfate, forming resveratrol glucuronides, sulfates, and/or sulfoglucuronides. Sulfate conjugates are the major forms of resveratrol metabolites found in plasma and urine in humans (7).

Preliminary studies found that the administration of single oral doses of 25 mg of *trans*-resveratrol to healthy volunteers resulted in peak blood concentrations of total resveratrol (i.e., *trans*-resveratrol plus its metabolites) around 60 minutes later, at about 1.8-2 µmoles/liter (µM), depending on whether resveratrol was administered in wine, vegetable juice, or grape juice (8, 9). A study in 40 healthy subjects who received single ascending doses of oral *trans*-resveratrol (i.e., 0.5 g, 1 g, 2.5 g, and 5 g) showed that plasma concentrations of unmetabolized resveratrol peaked between 0.8 and 1.5 hours after resveratrol administration at levels ranging from 0.3 µM to 2.3 µM (10). Of note, these values were markedly below those used to elicit chemopreventive effects of resveratrol in *in vitro* experiments (>5 µM). In contrast, following a single oral dose of 5 g of *trans*-resveratrol, the peak plasma concentrations of certain resveratrol conjugates were found to be about two to eight times higher than those of unmetabolized resveratrol (10). Also, compared to a single dose administration, the repeated intake of 5 g/day of *trans*-resveratrol for 29 days was found to result in significantly greater peak plasma concentrations of *trans*-resveratrol and two resveratrol glucuronide conjugates (11). Repeated doses of 1 g/day of *trans*-resveratrol (a dose less likely to cause side effects; see Safety) could yield maximum plasma concentrations of about 22 µM for resveratrol-3-O-sulfate (the most abundant sulfate conjugate in humans) and about 7-8 µM for typical monoglucuronide conjugates (12).

A few studies have examined the influence of food matrix on resveratrol absorption and/or bioavailability (reviewed in 13). One study has reported that bioavailability of *trans*-resveratrol from red wine did not differ when the wine was consumed with a meal (low- or high-fat) versus on an empty stomach (14). Yet, in another study, the absorption of supplemental resveratrol was found to be delayed, but not reduced, by the presence of food in the stomach (15). A third study found that the bioavailability of supplemental resveratrol was reduced by the amount of fat in the diet, but not by the co-administration of quercetin (another polyphenol) or alcohol (16).

Information about the bioavailability of resveratrol in humans is important because most of the experimental research conducted to date has been 'preclinical,' i.e., *in vitro*, exposing cells to resveratrol concentrations up to 100 times greater than peak plasma concentrations observed in humans, and in animal models given very high (non dietary) doses of resveratrol (13). While cells that line the digestive tract are exposed to unmetabolized resveratrol, other tissues are likely exposed to resveratrol metabolites. At present, little is known about the biological activity of resveratrol metabolites. Yet, if some tissues are capable of converting resveratrol metabolites back to resveratrol, stable resveratrol conjugates in tissues could serve as a pool in the body from which resveratrol might be regenerated (6, 12).

Biological Activities

The biological significance of resveratrol has been primarily investigated in test tubes and cultured cells, and to a lesser extent, in animal models. Of note, a recent publication by Tomé-Carneiro et al. (13) thoroughly reviewed the most relevant preclinical studies published in the most recent decades. It is important to keep in mind that many of the biological activities discussed below were observed in cells cultured in the presence of resveratrol at higher concentrations than those likely to be achieved in humans consuming resveratrol orally (see Metabolism and Bioavailability).

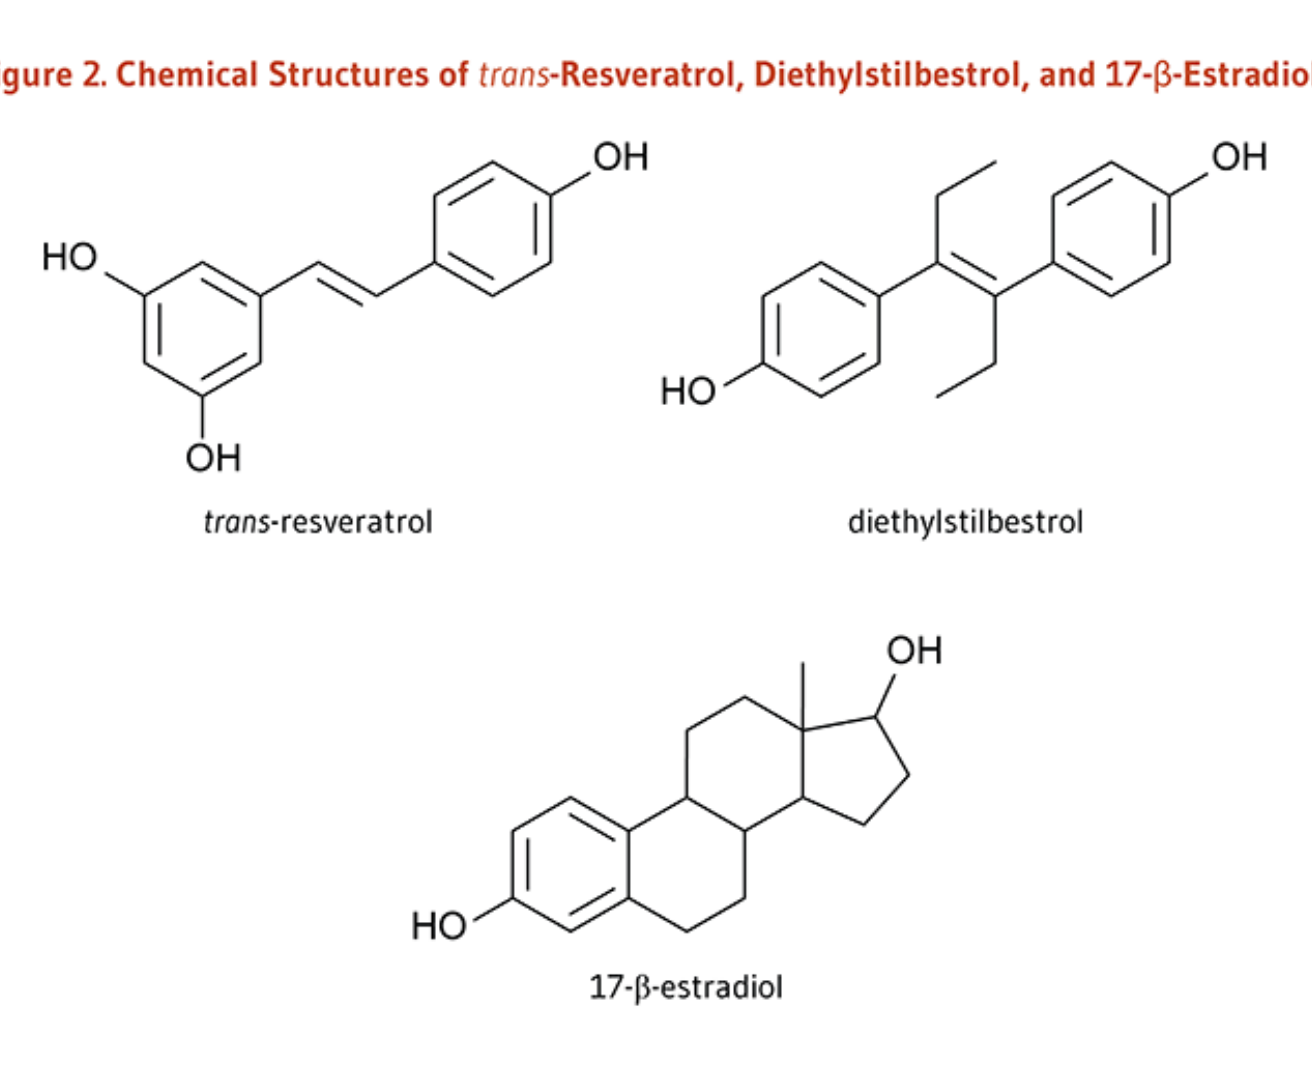
Direct antioxidant activity

In the test tube, resveratrol effectively scavenges (neutralizes) free radicals and other oxidants (17, 18) and inhibits low-density lipoprotein (LDL) oxidation (19, 20). Resveratrol was found to induce antioxidant enzymes, including superoxide dismutase (SOD), thioredoxin, glutathione peroxidase-1, heme oxygenase-1, and catalase, and/or inhibit reactive oxygen species (ROS) production by nicotinamide adenine dinucleotide phosphate (NADPH) oxidases (NOX) (21). However, there is little evidence that resveratrol is an important antioxidant *in vivo*. Upon oral consumption of resveratrol, circulating and intracellular levels of resveratrol in humans are likely to be much lower than that of other important antioxidants, such as vitamin C, uric acid, vitamin E, and glutathione. Moreover, the antioxidant activity of resveratrol metabolites, which comprise most of the circulating resveratrol, may be lower than that of resveratrol (22).

Estrogenic and anti-estrogenic activities

Endogenous estrogens are steroid hormones synthesized by humans and other mammals; these hormones bind to estrogen receptors within cells. The estrogen-receptor complex interacts with unique sequences in DNA (estrogen response elements; EREs) to modulate the expression of estrogen-responsive genes (23). The chemical structure of resveratrol is very similar to that of the synthetic estrogen agonist, diethylstilbestrol (**Figure 2**), suggesting that resveratrol might also function as an estrogen agonist, i.e., might bind to estrogen receptors and elicit similar responses to endogenous estrogens. However, in cell culture experiments, resveratrol was found to act either as an estrogen agonist or as an estrogen antagonist depending on such factors as cell type, estrogen receptor isoform (ERα or ERβ), and the presence of endogenous estrogens (23). Most recently, resveratrol was shown to improve endothelial wound healing through an ERα-dependent pathway in an animal model of arterial injury (24).

Figure 2. Chemical Structures of *trans*-Resveratrol, Diethylstilbestrol, and 17-β-Estradiol



Biological activities related to cancer prevention

Effects on biotransformation enzymes

Some compounds are not carcinogenic until they have been metabolized in the body by phase I biotransformation enzymes, especially cytochrome P450 enzymes (2). By inhibiting the expression and activity of certain cytochrome P450 enzymes (25, 26), resveratrol might help prevent cancer by limiting the activation of procarcinogens. In contrast, increasing the activity of phase II detoxification enzymes generally promotes the excretion of potentially toxic or carcinogenic chemicals. Resveratrol has been found to increase the expression and activity of NAD(P)H:quinone oxidoreductase-1 (NQO1) in cultured cells (27) and may be a weak inducer of other phase II enzymes (28).

Inhibition of proliferation and induction of apoptosis

Following DNA damage, the cell cycle can be transiently arrested to allow for DNA repair or activation of pathways leading to cell death (apoptosis) if the damage is irreparable (29). Defective cell cycle regulation may result in the propagation of mutations that contribute to the development of cancer. Moreover, unlike normal cells, cancer cells proliferate rapidly and are unable to respond to cell death signals that initiate apoptosis. Resveratrol has been found to induce cell cycle arrest and/or apoptosis (programmed cell death) in a number of cancer cell lines (reviewed in 13).

Inhibition of tumor invasion and angiogenesis

Cancerous cells invade normal tissue aided by enzymes called matrix metalloproteinases. Resveratrol has been found to inhibit the activity of at least one type of matrix metalloproteinase (30, 31). To fuel their rapid growth, invasive tumors must also develop new blood vessels by a process known as angiogenesis. Resveratrol has been found to inhibit angiogenesis *in vitro* (32-34) and *in vivo* (35).

Anti-inflammatory effects

Inflammation promotes cellular proliferation and angiogenesis and inhibits apoptosis (36). Resveratrol has been found to inhibit the activity of several inflammatory enzymes *in vitro*, including cyclooxygenases and lipoxygenases (37, 38). Resveratrol may also inhibit pro-inflammatory transcription factors, such as NFκB or AP-1 (39, 40).

Biological activities related to cardiovascular disease prevention

Inhibition of vascular cell adhesion molecule (VCAM) expression

Atherosclerosis is an inflammatory process in which lipids deposit in plaques (known as atheromas) within arterial walls and increase the risk of myocardial infarction (41). One of the earliest events in the development of atherosclerosis is the recruitment of inflammatory white blood cells from the blood to the arterial wall by vascular cell adhesion molecules (42). Resveratrol has been found to inhibit the expression of adhesion molecules in cultured endothelial cells (43, 44).

Inhibition of vascular smooth muscle cell (VSMC) proliferation

The proliferation of vascular smooth muscle cells (VSMCs) plays an important role in the progression of hypertension, atherosclerosis, and restenosis (when treated arteries become blocked again). Resveratrol has been found to inhibit the proliferation of VSMCs in culture (45-47), as well as *in vivo* (48). Resveratrol appeared to reduce VSMC proliferation via an ERα-dependent mechanism, hence preventing the narrowing of vessels in a mouse model of arterial injury (48).

Stimulation of endolethelial nitric oxide synthase (eNOS) activity

Endothelial nitric oxide synthase (eNOS) is an enzyme that catalyzes the formation of nitric oxide (NO) by vascular endothelial cells. NO is needed to maintain arterial relaxation (vasodilation), and impaired NO-dependent vasodilation is associated with an increased risk of cardiovascular disease (49). Because physiological concentrations of resveratrol were found to stimulate eNOS activity in cultured endothelial cells (50-52), resveratrol might help maintain or improve endothelial function *in vivo* (see Cardiovascular disease).

Inhibition of platelet activiation and aggregation

Platelet aggregation is one of the first steps in the formation of a blood clot that can occlude a coronary or cerebral artery, resulting in myocardial infarction or stroke, respectively. Resveratrol has been found to inhibit platelet activation and aggregation *in vitro* (53-55).

Biological activities related to neurodegenerative disease prevention and treatment

Stimulation of neurogenesis and microvessel formation

Age-related mood alterations and memory deficits result from a decrease in the function of the hippocampus in the elderly. Resveratrol was shown to stimulate neurogenesis and blood vessel formation in the hippocampus of healthy old rats. These structural changes were associated with significant improvements in spatial learning, memory formation, and mood function (56).

Stimulation of β-amyloid peptide clearance

One feature of Alzheimer's disease (AD) is the accumulation of β-amyloid peptide into senile (amyloid) plaques outside neurons in the hippocampus and cortex of AD patients (57). Senile plaques are toxic to cells, resulting in progressive neuronal dysfunction and death. Resveratrol was found to facilitate the clearance of β-amyloid peptide and promote cell survival in primary neurons in culture and neuronal cell lines (58-60). Resveratrol also reduced senile plaque counts in various brain regions of a transgenic AD mouse model (61).

Inhibition of neuroinflammation

Abnormally activated microglia and hypertrophic astrocytes around the senile plaques in AD brains release cytotoxic molecules, such as proinflammatory mediators and ROS, which enhance the formation and deposition of β-amyloid peptides and further damage neurons (57). Resveratrol was found able to inhibit the inflammatory response triggered by β-amyloid peptide-induced microglial activation in microglial cell lines and in a mouse model of cerebral amyloid deposition (62). A decreased occurrence of microglial activation and astrocyte hypertrophy was also reported in healthy aged rats treated with resveratrol (56).

Reduction of oxidative stress

Mitochondrial dysfunction and oxidative stress are thought to be involved in the etiology and/or progression of several neurodegenerative disorders (63). Resveratrol counteracted oxidative stress and β-amyloid peptide-induced toxicity in cultured neuroblastoma (64). Resistance against oxidative stress-related damage in primary neuronal cells treated with resveratrol has been associated with the induction of heme oxygenase-1 (HO-1), an enzyme that degrades pro-oxidant heme (65). In an experimental model of stroke, resveratrol limited infarct size during ischemia-reperfusion in wild-type mice but not in mice lacking the HO-1 gene (66). Also, resveratrol was able to correct experimentally induced oxidative stress and the associated cognitive dysfunction in rats (67).

Disease Prevention

Cancer

Resveratrol has been found to inhibit the proliferation of a variety of human cancer cell lines, including those from breast, prostate, stomach, colon, pancreatic, and thyroid cancers (2). In animal models, oral administration, topical application, and/or injection of resveratrol inhibited the development of chemically-induced cancer at many sites, including gastrointestinal tract, liver, skin, breast, prostate, and lung (reviewed in 68, 69). The anti-cancer effects of resveratrol in rodent models involved the reduction of cell proliferation, the induction of apoptosis, and the inhibition of angiogenesis, tumor growth, and metastasis (reviewed in 13). Yet, a few animal studies have reported a lack of an effect of oral resveratrol in inhibiting the development of lung cancer induced by carcinogens in cigarette smoke (70, 71), and the study of resveratrol administration on colon cancer has given mixed results (72-74).

At present, it is not known whether resveratrol might be beneficial in the prevention and/or the treatment of cancer in humans. The low bioavailability of resveratrol reported in human studies limits the clinical evaluation of possible systemic health effects of resveratrol in humans (see Metabolism and Bioavailability). Yet, in a pilot study, unmetabolized resveratrol and conjugates have been detected in colorectal tumor tissues from 20 cancer patients following daily oral supplementation with either 4 g or 8 g of resveratrol for 29 days. Resveratrol appeared to be well tolerated and significantly, though modestly, reduced cell proliferation compared to baseline (75). A micronized formulation of resveratrol (named SRT501), which was meant to increase resveratrol delivery to target tissues, was given for 14 days to 6 patients with colorectal cancer and liver metastasis in a small randomized, double-blind, placebo-controlled trial (76). Unmetabolized resveratrol was measurable in the liver of five out of six patients who consumed 5 g of SRT501, and SRT501 administration resulted in an increased detection of the apoptotic marker, cleaved caspase-3, in hepatic tumor tissues. Yet, in an unrandomized and unblinded trial in patients with multiple myeloma, the administration of SRT501 was associated with a number of serious adverse effects, including kidney failure, such that the trial was halted (77). Since kidney failure is a frequent complication in myeloma patients, it is unclear whether kidney failure cases should be solely attributed to the use of SRT501. Nevertheless, there is a need to find safe ways to increase resveratrol bioavailability in humans before exploring its putative benefits in clinical settings (6, 78).

Cardiovascular disease

Red wine polyphenols

Significant reductions in cardiovascular disease risk have been associated with moderate consumption of alcoholic beverages (79). The "French Paradox" — the observation that incidence of coronary heart disease was relatively low in France despite high levels of dietary saturated fat and cigarette smoking — led to the idea that regular consumption of red wine might provide additional protection from cardiovascular disease (80). Red wine contains variable and usually low concentrations of resveratrol (see Sources) and higher concentrations of flavonoids like procyanidins. These polyphenolic compounds have displayed antioxidant, anti-inflammatory, and other potentially anti-atherogenic effects in the test tube and in some animal models of atherosclerosis (81). The results of epidemiological studies addressing this question have been inconsistent. While some large prospective cohort studies found that wine drinkers were at lower risk of cardiovascular disease than beer or liquor drinkers (82-84), others found no difference (85-87). Socioeconomic and lifestyle differences between people who prefer wine and those who prefer beer or liquor may explain part of the additional benefit observed in some studies: people who prefer wine tend to have higher incomes, more education, smoke less, and eat more fruit and vegetables and less saturated fat than those who prefer other alcoholic beverages (87-92).

Although moderate alcohol consumption has been consistently associated with reductions in coronary heart disease risk, it is not yet clear whether red wine polyphenols confer any additional risk reduction. Interestingly, studies that administered alcohol-free red wine to rodents noted improvements in various parameters related to cardiovascular disease (93, 94), and a placebo-controlled human study found that heart disease patients administered red grape polyphenol extract experienced acute improvements in endothelial function (95). Whether increased consumption of polyphenols from red wine provides any additional cardiovascular benefits beyond those associated with red wine's alcohol content needs to be further examined (see the article on Alcoholic Beverages) (96).

Resveratrol and endothelial function

Endothelial dysfunction is usually associated with the presence of cardiovascular risk factors (e.g., insulin resistance, hypertension, and hypercholesterolemia) and is thought to precede the clinical manifestation of cardiovascular and metabolic disorders. Endothelial dysfunction is characterized by abnormal vasoconstriction, leukocyte adherence to vascular endothelial cells, platelet activation and aggregation, smooth muscle cell proliferation, vascular inflammation, thrombosis (clot formation), impaired coagulation, and atherosclerosis (97).

Experimental studies: Resveratrol has been found to exert a number of protective effects on the cardiovascular system *in vitro*, including inhibition of both platelet activation and aggregation (53, 98, 99), promotion of vasodilation by enhancing the production of nitric oxide (NO) (52), and control of the production of inflammatory lipid mediators (38, 100, 101). However, the concentrations of resveratrol required to produce these effects are often higher than those measured in human plasma after oral consumption of resveratrol (9). Some animal studies also suggested that high oral doses of resveratrol could decrease the risk of thrombosis and atherosclerosis (102, 103), although one study found increased atherosclerosis in animals fed resveratrol (104). Other protective effects of resveratrol *in vivo* include the reduction of cardiac hypertrophy and the lowering of blood pressure in various models, as well as the limitation of infarct size in post myocardial infarction rats (reviewed in 13).

Randomized controlled studies: In a six-month, cross-over study, 34 patients with metabolic syndrome were randomized to receive resveratrol (100 mg/day) for three months either immediately at the beginning of the study or three months later. Resveratrol supplementation resulted in improved values of flow-mediated dilation (FMD) of the brachial artery, a surrogate marker of vascular health. Yet, FMD returned to baseline values within three months after discontinuing resveratrol (105). One study limitation was that the resveratrol formulation contained additional compounds (i.e., vitamin D_3, quercetin, and rice bran phytate), which may also affect endothelial function. One randomized, placebo-controlled study in healthy overweight or obese volunteers (BMI, 25-34 kg/m^2) found that a single dose of *trans*-resveratrol (30 mg, 90 mg, or 270 mg) improved brachial FMD around 60 minutes after administration (106). In a second study, the same investigators found that FMD improvements were similar whether participants had received a single dose of resveratrol (75 mg) or a daily dose (75 mg/day of resveratrol) for six months (107).

In a few additional studies, resveratrol was shown to improve endothelial function by reducing vascular inflammation and endothelial activation. A randomized, double-blind, placebo-controlled study in 41 healthy subjects found that daily supplementation with resveratrol (400 mg), grapeseed extract (400 mg), and quercetin (100 mg), for one month significantly reduced the expression of interleukin-8 (IL-8) and cell adhesion molecules (ICAM-1 and VCAM-1) in endothelial cells, suggestive of a protective effect against endothelial dysfunction (108). The daily intake of a resveratrol-rich grape supplement was compared to resveratrol-free grape supplement in a year-long, randomized, double blind, placebo-controlled study in 75 individuals at high risk for cardiovascular disease (CVD). Administration of the resveratrol-rich supplement (resveratrol: 8 mg/day for 6 months, then 16 mg/day for another 6 months) significantly improved the profile of circulating inflammatory markers, reducing levels of C-reactive protein (CRP) and Tumor Necrosis Factor-α (TNF-α), as well as the level of thrombogenic factor, Plasminogen Activator Inhibitor-1 (PAI-1) (109). The decreased concentrations of two CVD risk markers, oxidized low-density lipoprotein (oxLDL) and apolipoprotein B (ApoB) after six months further suggested a cardioprotective effect of resveratrol (110). Supplementation of patients with stable coronary heart disease with the same regimen also improved the profile of circulating inflammatory markers and reduced the expression of proinflammatory genes in peripheral blood mononuclear cells (PBMCs) (111). The expression of microRNAs and cytokines specifically involved in atherogenic and pro-inflammatory signals were also found to be downregulated in the PBMCs of supplemented patients (112). Finally, although it is not clear whether hypertension is a cause or an effect of endothelial dysfunction, a recent meta-analysis of randomized controlled trials suggested that high doses of resveratrol (≥150 mg/for at least one month) might help lower systolic blood pressure in individuals at risk for CVD (113).

While preliminary human studies suggest that resveratrol may have beneficial effects on cardiovascular health, there is currently no convincing evidence that these effects can be achieved in the amounts present in one to two glasses of red wine (see Sources). For more information regarding resveratrol and cardiovascular disease, see (114).

Longevity

Caloric restriction is known to extend the lifespan of a number of species, including yeast, worms, flies, fish, rats, and mice (115). In yeast (*Saccharomyces cerevisiae*), caloric restriction stimulates the activity of an enzyme known as Silent information regulator 2 protein (Sir2) or sirtuin (116). Yeast Sir2 is a nicotinamide adenine dinucleotide (NAD)-dependent deacetylase enzyme that removes the acetyl group from acetylated lysine residues in target proteins (see the article on Niacin).

Providing resveratrol to yeast increased Sir2 activity in the absence of caloric restriction and extended the replicative (but not the chronological) lifespan of yeast by 70% (117). Resveratrol feeding also extended the lifespan of worms (*Caenorhabditis elegans*) and fruit flies (*Drosophila melanogaster*) by a similar mechanism (118). Additionally, resveratrol dose-dependently increased the lifespan of a vertebrate fish (*Nothobranchius furzeri*) (119). Resveratrol was also found to extend the lifespan of mice on a high-calorie diet such that their lifespan was similar to that of mice fed a standard diet (120). Although resveratrol increased the activity of the Sir2 homologous human sirtuin 1 (SIRT1) in the test tube (117), there are no epidemiological data to link resveratrol, SIRT1 activation, and extended human lifespan. Moreover, the supraphysiological concentrations of resveratrol required to increase human SIRT1 activity were considerably higher than concentrations that have been measured in human plasma after oral consumption.

The results of a nine-year prospective cohort study in over 700 older adults (≥65 years) indicated that participants who were alive at the end of the study had baseline concentrations of total urinary resveratrol metabolites (used as a biomarker of resveratrol intake) similar to those who died during the study period (121). Based on a lack of correlation with baseline inflammatory markers, cardiovascular disease and cancer incidence, and all-cause mortality, the authors concluded that higher versus lower quartiles of urinary resveratrol metabolite concentrations did not predict risk of chronic disease or mortality. However, key experts identified several limitations regarding the quality of the research (122, 123). Specifically, the use of single measures of total urinary resveratrol metabolites at baseline has been highlighted as being unlikely to reflect lifetime consumption of wine or exposure to dietary resveratrol (122).

Cognitive decline

In a mouse model of Alzheimer's disease (AD), caloric restriction has been shown to limit the production and deposition of neurotoxic β-amyloid peptide in the brain (124). Similar to the effect of caloric restriction, resveratrol was found to improve obesity and diabetes-related metabolic deregulations via the activation of metabolic sensors, including SIRT and the AMP-activated protein kinase (AMPK) (125), as well as to promote the AMPK-dependent clearance of β-amyloid peptide in the brain of an AD mouse model (60). Resveratrol has also exhibited additional neuroprotective properties in cultured cells and animal models (see Biological Activities).

Although resveratrol bioavailability to the brain is uncertain (78), a randomized, double-blind, placebo-controlled study has reported an increase in cerebral blood flow in the prefrontal cortex of healthy young subjects (ages, 18-29 years) following a single oral dose of 500 mg of resveratrol. However, resveratrol intake did not improve performance in cognitively demanding tasks undertaken during the post-administration period (126). More recently, the co-administration of resveratrol (200 mg/day) and quercetin (320 mg/day) for 26 weeks in a double-blind, placebo-controlled study significantly improved measures of memory function and enhanced blood glucose control in 46 healthy, overweight older adults (ages, 50-80 years; BMI, 25-30 kg/m^2) (127). Additional evidence of the potential of resveratrol to mimic the metabolic benefits of caloric restriction on cognitive health may come from ongoing clinical trials in both healthy older individuals and AD patients (128).

Disease Treatment

Impaired glucose tolerance and type 2 diabetes mellitus

More than one out of three American adults has impaired glucose tolerance (also known as prediabetes), which places them at increased risk of developing type 2 diabetes (129). Impaired glucose tolerance is associated with insulin resistance in skeletal muscle — the major peripheral tissue for insulin-mediated glucose uptake — as well as defective insulin secretion by pancreatic β-cells. Muscle insulin resistance, which is thought to be the earliest stage in the development of type 2 diabetes, is characterized by excess lipid exposure, impaired insulin receptor signaling, impaired glucose uptake, mitochondrial dysfunction, reduced fatty acid oxidation, and increased expression of pro-inflammatory cytokines.

In animal studies, resveratrol has been shown to improve insulin sensitivity, glucose tolerance, and lipid profiles in obese and/or metabolically abnormal animals (reviewed in 130).

In humans, short-term supplementation with resveratrol has been associated with beneficial effects on glucose and lipid metabolism in individuals with type 2 diabetes. In a randomized, double-blind, placebo-controlled study, the effect of oral resveratrol supplementation (1,000 mg/day for 45 days) on the control of glucose metabolism was assessed in 70 subjects with type 2 diabetes (131). Comparison of changes between baseline and end-of-study measures between placebo and intervention groups showed that resveratrol significantly lowered both fasting glucose and fasting insulin concentrations and improved measures of glycemic control (HbA1c level) and insulin sensitivity (HOMA-IR). In addition, the level of HDL-cholesterol was increased while the level of LDL-cholesterol and systolic blood pressure were significantly reduced. No changes were found in measures of diastolic blood pressure, total cholesterol, triglycerides, and markers of liver function (131). Additionally, in a randomized, open-label, and controlled study, the effect of oral resveratrol (250 mg/day) on glycemic control and lipid metabolism was assessed in 62 type 2 diabetics (132). During the three-month study period, changes in biochemical and clinical parameters, including fasting glucose concentration, HbA1c level, systolic and diastolic blood pressure, total cholesterol, and LDL-cholesterol, were significantly improved with resveratrol compared to control (i.e., no resveratrol). Doses as low as 10 mg/day of resveratrol also resulted in lower insulin resistance in a four-week, randomized, placebo-controlled study in 19 male subjects with type 2 diabetes (133).

Obesity (defined as a body mass index [BMI] ≥ 30 kg/m^2) is a well-known risk factor for the development of type 2 diabetes. A few clinical studies have evaluated the effects of resveratrol on key metabolic variables in overweight or obese subjects with no overt metabolic dysfunction and found little or no metabolic benefits following resveratrol treatment (134-136). Yet, at present, there is no available evidence to suggest whether overweight or obese individuals with impaired glucose tolerance could benefit from resveratrol supplements and reduce their risk of developing type 2 diabetes (137).

Current data suggest that resveratrol could improve specific metabolic variables in individuals with type 2 diabetes (138, 139), but more research is needed to assess its effect in individuals at risk for diabetes, including obese subjects with impaired glucose tolerance.

Sources

Food sources

Resveratrol is found in grapes, wine, grape juice, peanuts, cocoa, and berries of *Vaccinium* species, including blueberries, bilberries, and cranberries (140-143). In grapes, resveratrol is found only in the skins (144). The amount of resveratrol in grape skins varies with the grape cultivar, its geographic origin, and exposure to fungal infection (145). The amount of fermentation time a wine spends in contact with grape skins is also an important determinant of its resveratrol content. Because grape skins are removed early during the production process of white and rosé wines, these wines generally contain less resveratrol than red wines (4). Therefore, because of variations between types of wine, vintages, and regions, it is very difficult to provide accurate estimates of resveratrol content in the thousands of wines from worldwide wineries. Yet, it appears that resveratrol content in wine is usually low, highly variable and unpredictable, and resveratrol is only a minor compound in the complete set of grape and wine polyphenols (13).

The predominant form of resveratrol in grapes and grape juice is *trans*-resveratrol-3-O-β-glucoside (*trans*-piceid), and wines contain significant amounts of resveratrol aglycones, thought to be the result of sugar cleavage during fermentation (3, 140). Many wines also contain significant amounts of *cis*-resveratrol (see **Figure 1** above), which may be produced during fermentation or released from viniferins (resveratrol polymers) (146). Red wine is a relatively rich source of resveratrol, but other polyphenols are present in red wine at considerably higher concentrations than resveratrol (see the article on Flavonoids) (147). Estimates of resveratrol content of some beverages and foods are listed in **Table 1** and **Table 2**. These values should be considered approximate since the resveratrol content of foods and beverages can vary considerably.

Table 1. Average *trans*-Resveratrol Content of Red Wines (148)

Variety	Lowest (mg/L)	Highest (mg/L)	Mean (mg/L)	5-oz Glass (mg)
Pinot Noir	0.2	11.9	3.6 ± 2.9	0.5
Merlot	0.3	14.3	2.8 ± 2.6	0.4
Zweigelt	0.6	4.7	1.9 ± 1.2	0.3
Shiraz	0.2	3.2	1.8 ± 0.9	0.3
Cabernet Sauvignon	-	9.3	1.7 ± 1.7	0.2
Red wines (global)	-	14.3	1.9 ± 1.7	0.3

Table 2. Total Resveratrol Content of Selected Foods (140, 142, 149)

Food	Serving	Total Resveratrol (mg)
Peanuts (raw)	1 cup (146 g)	0.01-0.26
Peanuts (boiled)	1 cup (180 g)	0.32-1.28
Peanut butter	1 cup (258 g)	0.04-0.13
Red grapes	1 cup (160 g)	0.24-1.25

Supplements

Most resveratrol supplements available in the US contain extracts of the root of *Polygonum cuspidatum*, also known as *Fallopia japonica*, Japanese knotweed, or Hu Zhang (150). Red wine extracts and grape extracts (from *Vitis vinifera*) containing resveratrol and other polyphenols are also available as dietary supplements. Resveratrol supplements may contain anywhere from less than 1 milligram (mg) to 500 mg of resveratrol per tablet or capsule, but it is not known whether there is a safe and effective dosage for chronic disease prevention in humans (also see the section on Safety).

Safety

Adverse effects

In rats, daily oral administration of *trans*-resveratrol at doses up to 700 mg/kg of body weight for 90 days resulted in no apparent adverse effects (151). Other toxicity studies conducted in animal models estimated that the no-observed-adverse-effect-level (NOAEL) for resveratrol was 200 mg/kg/days and 600 mg/kg/day in rats and dogs, respectively (152). Resveratrol is not known to be toxic or cause significant adverse effects in humans, but there have been only a few controlled clinical trials to date (reviewed in 153). A trial evaluating the safety of oral *trans*-resveratrol in 10 subjects found that a single dose of 5,000 mg resulted in no serious adverse effects (10). In a follow-up study, mild-to-moderate gastrointestinal side effects, including nausea, abdominal pain, flatulence, and diarrhea, have been reported in participants who consume more than 1,000 mg/day of resveratrol for up to 29 consecutive days (11). Mild diarrhea was also reported in six out of eight individuals who consumed 2,000 mg of resveratrol twice daily for two periods of eight days in an open-label and within subject-control study (16).

Pregnancy and lactation

The safety of resveratrol-containing supplements during pregnancy and lactation has not been established (150). Because there is no known safe amount of alcohol consumption at any stage of pregnancy (154), pregnant women should avoid consuming wine as a source of resveratrol.

Estrogen-sensitive conditions

Until more is known about the estrogenic activity of resveratrol in humans, women with a history of estrogen-sensitive cancers, such as breast, ovarian, and uterine cancers, should avoid resveratrol supplements (see Estrogenic and anti-estrogenic activities) (150).

Drug interactions

Anticoagulant and antiplatelet drugs

Resveratrol has been found to inhibit human platelet aggregation *in vitro* (53, 155). Theoretically, high intakes of resveratrol (i.e., from supplements) could increase the risk of bruising and bleeding when taken with anticoagulant drugs, such as warfarin (Coumadin) and heparin; antiplatelet drugs, such as clopidogrel (Plavix) and dipyridamole (Persantine); and non-steroidal anti-inflammatory drugs (NSAIDs), including aspirin, ibuprofen, diclofenac, naproxen, and others.

Drugs metabolized by cytochrome P450

Cytochrome P450 (CYP) enzymes are phase I biotransformation enzymes involved in the metabolism of a broad range of compounds, from endogenous molecules to therapeutic agents. The most abundant CYP isoform in the human liver and intestines is cytochrome P450 3A4 (CYP3A4), which catalyzes the metabolism of about half of all marketed drugs in the US (156). Resveratrol has been reported to inhibit CYP3A4 activity *in vitro* (157, 158) and in healthy volunteers (28). Therefore, high intakes of resveratrol (i.e., from supplements) could potentially reduce the metabolic clearance of drugs that undergo extensive first-pass metabolism by CYP3A4, hence increasing the bioavailability and risk of toxicity of these drugs. Some of the many drugs metabolized by CYP3A4 include HMG-CoA reductase inhibitors (statins), calcium channel antagonists (felodipine, nicardipine, nifedipine, nisoldipine, nitrendipine, nimodipine, and verapamil), anti-arrhythmic agents (amiodarone), HIV protease inhibitors (saquinavir), immunosuppressants (cyclosporine and tacrolimus), antihistamines (terfenadine), benzodiazepines (midazolam and triazolam), and drugs used to treat erectile dysfunction (sildenafil). Of note, a recently completed clinical trial (NCT01173640) examined the potential for single and multiple doses of resveratrol (1,000 mg) to interfere with the metabolism of midazolam in healthy volunteers, and results are soon to be published (153). Other CYP enzymes (e.g., CYP2D6 and CYP2C9) may also be inhibited by resveratrol (reviewed in 159).

Finally, resveratrol was found to be a weak inducer of the expression and activity of CYP1A2, which catalyzes the metabolism of several drugs, including acetaminophen (paracetamol) and the antidepressant drugs, clomipramine and imipramine (28, 156). This suggests that resveratrol may interfere with CYP1A2-mediated drug metabolism by increasing drug clearance, possibly lowering circulating drug concentrations below therapeutic levels.

Summary

- Isoflavones are a class of phytoestrogens — plant-derived compounds with estrogenic activity. Soybeans and soy products are the richest sources of isoflavones in the human diet. *(More information)*
- Some health effects of soy may be dependent on one's capacity to convert the isoflavone daidzein to equol during digestion. *(More information)*
- The results of observational studies suggest that higher intakes of soy foods early in life may decrease the risk of breast cancer in adulthood. There is currently little clinical evidence that taking soy isoflavone supplements decreases the risk of incident and recurrent breast cancer. *(More information)*
- Current evidence from observational studies and small clinical trials is not robust enough to understand whether soy protein/isoflavone supplements may help prevent or inhibit the progression of prostate cancer. *(More information)*
- To date, randomized controlled trials examining the effect of soy isoflavones on bone mineral density in postmenopausal women have produced mixed results. Potential benefits of soy isoflavones as an alternative to bone-sparing treatments in women undergoing menopause remain to be determined. *(More information)*
- Current evidence suggests that whole soy components other than isoflavones may have favorable effects on serum lipid profiles. Yet, two recent meta-analyses of randomized controlled trials indicated that isoflavones might exert cardiovascular benefits by improving vascular function in postmenopausal women. *(More information)*
- Supplementation with isoflavones appeared to be about 40% less efficient than hormone-replacement therapy in attenuating menopausal hot flashes and required more time to reach its maximum effect. Yet, supplements containing primarily the isoflavone genistein have demonstrated consistent alleviation of menopausal hot flashes. *(More information)*
- Currently available data suggest that breast cancer survivors should not be further discouraged from consuming soy foods in moderation. Moreover, in a pooled analysis of three large prospective cohort studies, soy isoflavone intake ≥10 mg/day was associated with a 25% reduced risk of tumor recurrence in breast cancer survivors. *(More information)*
- At present, there is no convincing evidence that infants fed soy-based formula are at greater risk for adverse effects than infants fed cow's milk-based formula. *(More information)*

Introduction

Isoflavones are polyphenolic compounds that possess both estrogen-agonist and estrogen-antagonist properties (see Biological Activities). For this reason, they are classified as phytoestrogens — plant-derived compounds with estrogenic activity (1). Isoflavones are the major flavonoids found in legumes, particularly soybeans. In soybeans, isoflavones are present as glycosides, i.e., bound to a sugar molecule. Digestion or fermentation of soybeans or soy products results in the release of the sugar molecule from the isoflavone glycoside, leaving an isoflavone aglycone. Soy isoflavone glycosides include genistin, daidzin, and glycitin, while the aglycones are called genistein, daidzein, and glycitein (**Figure 1**). Unless otherwise indicated, quantities of isoflavones specified in this article refer to aglycones — not glycosides.

Metabolism and Bioavailability

The article on Flavonoids describes some of the factors influencing the absorption, metabolic fate, and bioavailability of flavonoid family members, including isoflavones. Pharmacokinetic studies have indicated that plasma concentrations of daidzein and genistein peaked about six hours after isoflavone intake, preceded by a smaller initial peak one hour post-meal (2, 3). The initial peak reflects isoflavone absorption following the hydrolysis of isoflavone glycosides to aglycones by β-glucosidases in the small intestine, while the second peak corresponds to isoflavone aglycones absorbed after the hydrolysis of glycosides by bacterial β-glucosidases in the colon (2).

The composition of one's colonic microbiota can influence the metabolic fate and biological effects of isoflavones. Indeed, the extent of at least some of the potential health benefits of soy intake are thought to depend on one's capacity to convert isoflavones to key metabolites during digestion. Specifically, some colonic bacteria can convert the soy isoflavone daidzein to equol, a metabolite that has greater estrogenic activity than daidzein, and to other metabolites, such as *O*-desmethylangolensin [*O*-DMA], that are less estrogenic (**Figure 2**) (4, 5). Equol appears in plasma about eight hours after isoflavone intake owing to the transit time of daidzein to the colon and its subsequent conversion to equol by the microbiota. Studies measuring urinary equol excretion after soy consumption indicated that equol was produced by about 25%-30% of the adult population in Western countries compared to 50%-60% of adults living in Asian countries and Western adult vegetarians (4, 6). Note that individuals possessing equol-producing bacteria are called "equol producers" as opposed to "equol non-producers."

Although prolonged soy food consumption has not been associated with the ability to produce equol, the type of soy food consumed might influence the composition of microbiota to include equol-producing bacteria (discussed in 4).

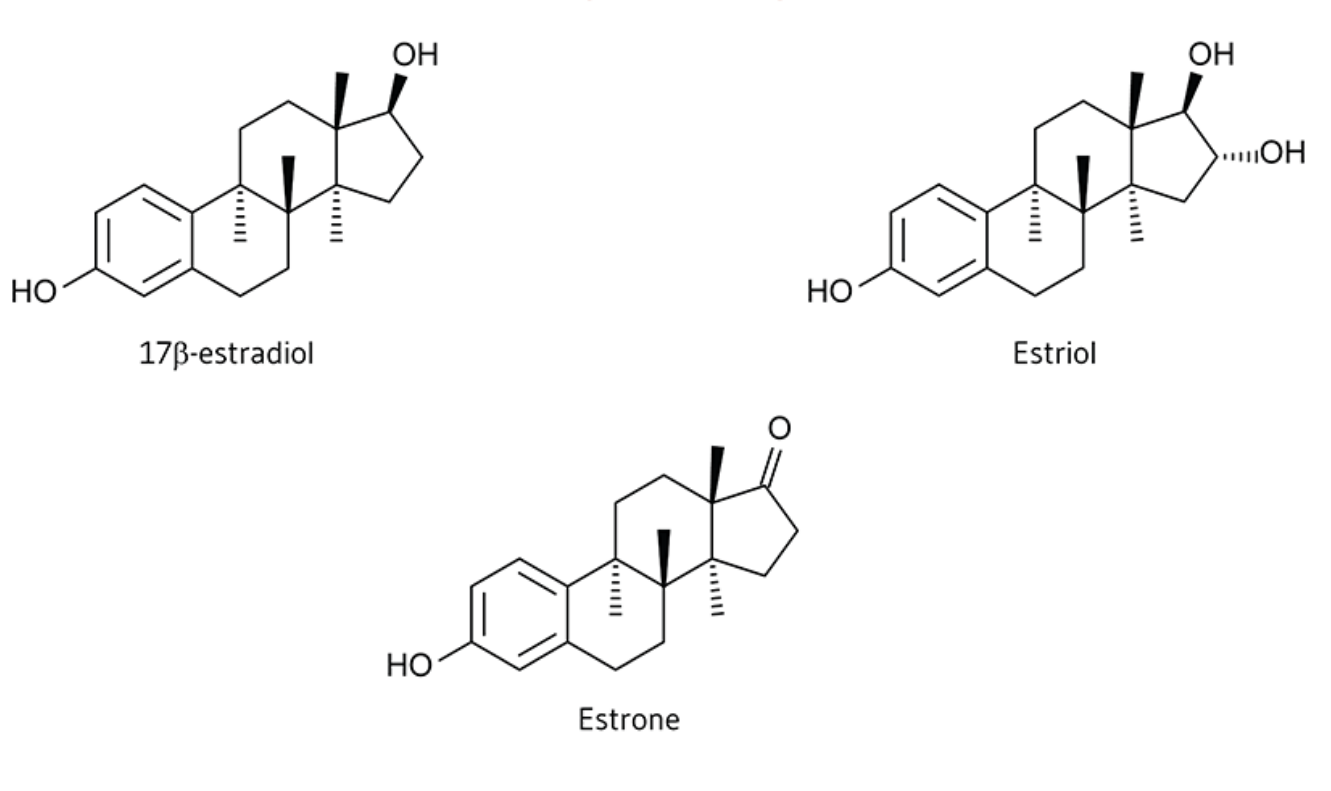
Biological Activities

Estrogenic and anti-estrogenic activities

Soy isoflavones are known to have weak estrogenic or hormone-like activity due to their structural similarity with 17-β-estradiol (**Figure 3**). Estrogens are signaling molecules that exert their effects by binding to estrogen receptors within cells (**Figure 3**). The estrogen-receptor complex interacts with DNA to change the expression of estrogen-responsive genes. Estrogen receptors (ER) are present in numerous tissues other than those associated with reproduction, including bone, liver, heart, and brain (7). Soy isoflavones can preferentially bind to and transactivate estrogen receptor-β (ER-β) — rather than ER-α — mimicking the effects of estrogen in some tissues and antagonizing (blocking) the effects of estrogen in others (8). Scientists are interested in the tissue-selective activities of phytoestrogens because anti-estrogenic effects in reproductive tissue could help reduce the risk of hormone-associated cancers (breast, uterine, and prostate), while estrogenic effects in other tissues could help maintain bone mineral density and improve blood lipid profiles (see Disease Prevention). The extent to which soy isoflavones exert estrogenic and anti-estrogenic effects in humans is currently the focus of considerable scientific research.

Figure 3. Chemical Structures of Some Endogenous Estrogens



[Click to Enlarge]

Estrogen receptor-independent activities

Soy isoflavones and their metabolites also have biological activities that are unrelated to their interactions with estrogen receptors (9). By inhibiting the synthesis and activity of certain enzymes involved in estrogen metabolism, soy isoflavones may alter the biological activity of endogenous estrogens and androgens (10-13). Soy isoflavones have also been found to inhibit tyrosine kinases (14), enzymes that play critical roles in the signaling pathways that stimulate cell proliferation. Additionally, isoflavones can act as antioxidants *in vitro* (15), but the extent to which they contribute to the antioxidant status of humans is not yet clear. Plasma F$_2$-isoprostanes, biomarkers of lipid peroxidation *in vivo*, were significantly lower after two weeks of daily consumption of soy protein containing 56 mg of isoflavones than after consumption of soy protein providing only 2 mg of isoflavones (16). However, daily supplementation with 50 to 100 mg of isolated soy isoflavones did not significantly alter plasma or urinary F$_2$-isoprostane concentrations (17, 18).

Disease Prevention

Hormone-associated cancers

Since soy isoflavones are structurally similar to endogenous estrogens, it has been suggested that they might help protect against hormone-associated cancers.

Breast cancer

High isoflavone intake from soy foods in Asian countries (average range, 25 to 50 mg/day) has been suggested to contribute to reducing the risk of breast cancer; in contrast, the incidence of breast cancer remains elevated in Europe, North America, and Australia/New Zealand (19) where average isoflavone intakes in non-Asian women are generally less than 2 mg/day (20). Nevertheless, several hereditary and lifestyle factors likely also contribute to this difference (19, 21). In a meta-analysis of one prospective cohort study and seven case-control studies conducted in Asian populations and in Asian Americans, higher versus lower intakes of dietary soy isoflavones (≥20 mg/day vs. ≤5 mg/day) were found to be associated with a 29% reduced risk of breast cancer (22). In observational studies conducted in Western populations, median intake of soy isoflavones was reportedly low (0.3 mg/day) and not associated with a decreased risk of breast cancer (22, 23). Moreover, a lifelong exposure to isoflavones may be needed to lower the risk of developing breast cancer later in life (21). This would explain why moderate versus low intakes of isoflavones (10.8 mg/day vs. 0.23 mg/day; cohort followed for a median of 7.4 years) during adulthood was not associated with a reduced risk of breast cancer in British women enrolled in the European Prospective Investigation into Cancer and Nutrition (EPIC) study (24). A few case-control studies also reported that early soy exposure — during childhood and adolescence — might be associated with a lower risk of breast cancer later in life (25-28). Further, a meta-analysis of four prospective cohort studies suggested that high versus low isoflavone intakes might be associated with a modest reduction in risk of recurrence (RR=0.84, 95% CI: 0.71-0.99) in breast cancer survivors (see Safety for breast cancer survivors) (23).

While lower circulating estrogen concentrations have been linked to a lower risk of breast cancer in postmenopausal women (29), a meta-analysis of randomized controlled trials in this population found no effect of soy isoflavone supplementation on the circulating concentrations of estrogenic hormones, estradiol (21 studies) and estrone (7 studies), and of sex-hormone binding globulin (SHBG; 17 studies) (30). Another meta-analysis of seven randomized controlled trials in 1,287 women found no overall effect of soy isoflavones (40 to 120 mg/day) consumed for six months to three years on mammographic breast density, used as a surrogate marker of breast cancer risk (31). Subgroup analyses showed no effect in postmenopausal women (four studies) but a modest increase in breast density — of unclear clinical significance — in premenopausal women (five studies). Further, in a recent randomized, placebo-controlled trial, soy isoflavone supplementation (50 mg/day for one year) also failed to affect breast density in women (ages, 30 to 75 years) with breast cancer (32).

There is currently little evidence that taking soy isoflavone supplements decreases the risk of incident and recurrent breast cancer.

Endometrial cancer

It is thought that the development of endometrial (uterine) cancer could be related to prolonged exposure to unopposed estrogen, i.e., estrogen not counterbalanced with the hormone progesterone (33). Excess estrogen relative to progesterone may result in endometrial thickening, a potential biomarker of estrogen-induced proliferation and a predictor of endometrial carcinomas (34). Whether high intakes of isoflavones with anti-estrogenic activity in uterine tissue could be associated with a lower risk of endometrial cancer has been examined in a number of observational studies. A recent meta-analysis of two prospective cohort studies and eight case-control studies found the highest versus lowest quantile of isoflavone intake to be associated with a 19% lower risk of endometrial cancer (35). One of the two prospective studies included in the meta-analysis found no association between consumption of total soy foods, legumes, and tofu and risk of endometrial cancer in a cohort of 46,027 multiethnic US women (mean age at cohort entry, 61.6 years) followed for a median 13.6 years (36). Nevertheless, a 34% lower risk of endometrial cancer was found to be associated with the highest versus lowest quintile of total isoflavones (median intakes, 11.23 mg/1,000 kcal/day vs. 0.87 mg/1,000 kcal/day) in this cohort (36). In the second prospective study, no association was observed between the top versus bottom tertile of isoflavone intakes (median intakes, 63.2 mg/day vs. 17.7 mg/day) and the risk of endometrial cancer risk in 49,121 Japanese women (ages, 45 to 74 years) (37). Because the consumption of isoflavones is much lower in non-Asian versus Asian cohorts, comparisons among populations are quite problematic and limit the scope of pooled analyses of observational studies (38).

Finally, a recent meta-analysis of 23 randomized controlled trials found no overall effect of isoflavone supplementation (5 to 154 mg/day) for up to three years on endometrial thickness in postmenopausal women (39). Nevertheless, a subgroup analysis of 10 trials showed that supplementation of postmenopausal women with isoflavone doses >54 mg/day of isoflavones could significantly decrease endometrial thickness (39).

Although limited evidence from case-control studies showed an inverse relationship between consumption of soy foods and endometrial cancer, there is little evidence from intervention trials to suggest that taking soy isoflavone supplements could decrease the risk of endometrial cancer.

Prostate cancer

Incidence rates of prostate cancer are much higher in Northern America, Northern and Western Europe, Australia, and New Zealand compared to Asian countries, such as Japan and China, where isoflavone-rich soybeans are common components of the diet (19). Soy food consumption has been associated with a reduced risk of prostate cancer in recent pooled analyses of observational studies (40, 41). In a study of 19 men with prostate cancer, daily soy supplementation resulted in soy isoflavone concentrations six-fold higher in prostate tissue than in serum (42). The results of cell culture and animal studies have suggested a potential role for soy isoflavones in limiting the progression of prostate cancer (reviewed in 43).

A number of small, short-term randomized controlled interventions have examined the effect of soy foods/isoflavones on biomarkers of prostate cancer risk (44). Compared to supplementation with milk protein, consumption of a diet supplemented with soy protein isolate high in isoflavones (~107 mg/day) limited the rise in androgen receptor density in prostate tissue after six months but did not modify prostatic estrogen receptor-β expression or circulating sex steroid hormone profile in men at high risk of developing prostate cancer (45). In addition, dietary soy protein supplementation had no effect on prostate-specific antigen (PSA) in serum or markers of cell proliferation and apoptosis in premalignant tissue. Yet, supplemental soy protein isolate — regardless of isoflavone content — for six months resulted in a lower cancer incidence compared to milk control (46). In a multicenter, randomized, double-blind, placebo-controlled trial in 158 Japanese men (ages, 50 to 75 years) with negative prostate biopsy but rising serum PSA, supplemental isoflavones (60 mg/day) for one year had no effect on circulating concentrations of PSA and sex steroid hormones, or on the overall incidence of biopsy-detectable prostate cancer. However, prostate cancer incidence was found to be significantly lower with isoflavones compared to placebo in the subset of men aged 65 years and older (47).

Some trials found that supplementation with soy products, soy dietary proteins, or soy isoflavones could reduce or slow down the rising of serum PSA concentration in men with localized prostate cancer prior to therapy (48-50), as well as in those with PSA biochemical recurrence following radiotherapy and/or prostatectomy (51-53). However, other trials failed to show an effect of soy food/isoflavones on serum PSA in prostate cancer patients prior to (54, 55) or after therapy (56-58). Clinical studies have also failed to show a protective effect of soy isoflavones on circulating concentrations of sex hormones (testosterone, dihydrotestosterone, and estradiol) and sex hormone-binding globulin (SHBG) in patients with prostate cancer (44).

Pooled analyses of current data are hindered by the heterogeneity in soy/soy isoflavone preparations and dosage regimens in short-term interventions (mostly ≤6 months) in small sample-size trials. Therefore, despite a good safety profile for supplemental soy isoflavones and soy proteins in prostate cancer patients, larger randomized controlled trials with longer periods of intervention are required to assess whether soy isoflavones could influence the development and/or progression of prostate cancer.

More information about soy foods and prostate cancer risk may be found in the article on Legumes.

Osteoporosis

The decline in estrogen production that accompanies menopause places middle-aged women at risk of osteopenia and osteoporosis. The measurement of bone mineral density (BMD) loss by dual-energy X-ray absorptiometry is generally used in the diagnosis of osteoporosis (59). Whether the estrogenic properties of soy isoflavones might play any role in preserving bone health and preventing bone loss is unclear. To date, the results of observational and intervention studies examining the potential protection of soy isoflavones against BMD loss have been inconsistent. A recent review by Zheng et al. (60) discussed some potential factors relative to study design (e.g., intervention duration, isoflavone dosages) and target populations (e.g., ethnic and genetic differences, hormonal status) that could explain the conflicting study results.

For instance, the results of short-term (≤6 months) clinical trials assessing the effects of increased soy intake on biochemical markers of bone formation and bone resorption are inconsistent. Some controlled trials in postmenopausal women have found that increasing intakes of soy foods, soy protein, or soy isoflavones improved markers of bone resorption and formation (61-64) or attenuated bone loss (64, 65), but other trials have found no significant benefit of increasing soy intakes (66-69). Trials of longer duration also showed conflicting results. A meta-analysis of 10 randomized controlled trials (trial duration, 12 to 24 months) concluded that a mean dose of 87 mg/day of soy isoflavones resulted in no significant changes in lumbar spine, total hip, or femoral neck BMD of postmenopausal women (70).

Mixed results also emerged from studies conducted in different ethnic populations. Compared to Caucasian women, the incidence of hip fractures tend to be lower among Asian women who are habitual soy food consumers (71, 72), suggesting that long-term soy food consumption might protect against bone loss or osteoporotic fracture (73, 74). Moreover, pooled analyses combining intervention trials in Caucasian and Asian postmenopausal women reported significant increases in BMD with supplemental soy isoflavones (75-77). In contrast, a meta-analysis of 12 placebo-controlled trials in Caucasian postmenopausal women found no effect of soy isoflavone supplementation (dose range, 52 to 120 mg/day) for six months to three years on lumbar spine BMD (78).

The rate of bone loss is not linear during the 10-year period surrounding the final menstrual period and is especially increased during the menopausal transition, starting about one year before to two years after the final menstrual period. Surprisingly, the recent US Study of Women's Health Across the Nation (SWAN) that followed Black, White, Japanese, and Chinese women reported that Japanese women with the highest versus lowest tertile of dietary isoflavone intakes (median intakes, 36.3 mg/day versus 4 mg/day) had an increased rate of BMD loss during menopause transition (79). In other ethnic groups, no such associations could be found between habitual dietary isoflavone intakes and the rate of bone loss before, after, or during menopause transition (79). Most meta-analyses of randomized controlled trials to date have reported a weak, positive effect of supplemental soy isoflavones on BMD in postmenopausal women (70, 75-77). Yet, it remains to be elucidated whether supplementation with soy isoflavones might be of any benefit to perimenopausal/early postmenopausal women before the acute loss of estrogen or to older postmenopausal women with established osteoporosis (60).

Finally, some authors have proposed that the effect of soy isoflavones on bone health may be dependent on whether or not the individual produces the daidzein metabolite, equol (see Metabolism and Bioavailability) (80-84). However, a recent randomized controlled trial found that supplementation with soy isoflavones increased calcium retention capacity in postmenopausal women regardless of their equol-producing capacity (85).

At present, the clinical benefits of soy isoflavones as an alternative to bone-sparing treatments in women undergoing menopause remain to be determined.

Cardiovascular disease

To date, large prospective cohort studies, mainly in Asian populations, investigating whether habitual soy food/isoflavone consumption is related to the incidence of cardiovascular disease (CVD), including coronary heart disease (CHD), ischemic stroke, and myocardial infarction, have found mixed results. In the Japan Public Health Center-based Study (mean follow-up, 13.5 years), consumption of soy foods was associated with a reduced risk of stroke in Japanese women (ages, 40 to 59 years) — but not in men. In this cohort, the highest versus lowest quintile of soy isoflavone intakes was found to be associated with a 65% lower risk of ischemic stroke and a 63% lower risk of myocardial infarction in women (86). In addition, an early data analysis of 64,915 Chinese women (ages 40 to 70 years) enrolled in the Shanghai Women's Health Study (SWHS) found an inverse relationship between soy food intake and risk of incident CHD during a 2.5-year follow-up period (87). However, a higher soy protein intake was associated with a higher risk of incident CHD in 55,474 Chinese men (ages, 40 to 74 years) from the Shanghai Men's Health Study (SMHS; mean follow-up of 5.4 years) (88). Moreover, a recent report of the SWHS cohort followed for 10 years reported a 24% higher risk of ischemic stroke with the highest versus lowest quintile of isoflavone intakes (mean intakes of 59.4 mg/d versus 8.6 mg/day) (89). Nevertheless, nested case-control studies within both Shanghai prospective studies found no correlations between soy food intake and incident CVD events when measures of urinary isoflavonoids were used as a more objective estimate of isoflavone exposure compared to dietary assessment with food-frequency questionnaires (89, 90). Further, no significant associations were found between long-term soy food, soy protein, and soy isoflavone consumption and CHD-, stroke-, and total CVD-related mortality in a 14.7-year follow-up of 60,298 participants of the Singapore Chinese Health Study (91).

Low consumption of soy foods in Western cohorts makes it more difficult to analyze possible longitudinal associations between isoflavone intake and CVD incidence or mortality in these populations (92-95).

Cardiometabolic risk factors

A number of intervention studies have examined soy intake in relation to several cardiometabolic risk factors. A recent meta-analysis of randomized controlled trials concluded that intake of either soy products (i.e., whole soybeans, soy milk, nuts, oil, and flour), soy protein isolate, or soy isoflavones for one month to one year could significantly improve serum lipid profiles in healthy and hypercholesterolemic individuals by lowering circulating triglycerides, total cholesterol, and LDL-cholesterol, and by increasing HDL-cholesterol (96). Further analyses suggested that soy protein without isoflavones was more effective at lowering total and LDL-cholesterol than soy protein containing isoflavones, and the consumption of soy isoflavones alone (as supplements or extracts) showed no significant effects on serum lipid profiles (96). In addition, a meta-analysis of 18 randomized controlled studies indicated that neither soy foods nor soy isoflavones could lower blood homocysteine concentrations, a known risk factor for CVD, in high-risk middle-aged and older adults (97). Another meta-analysis of 14 randomized controlled studies reported a reduction in circulating C-reactive protein (CRP) — an inflammation marker associated with increased cardiovascular risk — following soy isoflavone intake (from soy foods or isoflavone extracts) in postmenopausal women with elevated baseline CRP concentrations (>2.2 mg/L) (98). In a recent six-month placebo-controlled intervention study in 253 postmenopausal equol-producing women with prehypertension, supplementation with whole soy — but not daidzein — improved lipid profiles and lowered the concentrations of CRP (99). Whether potential cardiovascular benefits of soy isoflavone intake depend on individuals' capacity to produce isoflavone metabolites (like equol) needs to be more closely examined.

Current evidence suggests that whole soy components other than isoflavones may have favorable effects on cardiometabolic risk factors.

Vascular function

The preservation of normal arterial function plays an important role in cardiovascular disease prevention. The ability of all types of blood vessels, including arteries, to dilate in response to nitric oxide (NO) produced by the endothelial cells that line their inner surface is compromised in people at high risk for cardiovascular disease (100). In the presence of cardiovascular risk factors (e.g., hypertension, hypercholesterolemia, hyperglycemia), impaired endothelial function results in widespread vasodilation and coagulation abnormalities and is considered to be an early step in the development of atherosclerosis. Measures of brachial flow-mediated dilation (FMD), a surrogate marker of endothelial function, have been found to be inversely associated with risk of future cardiovascular events (101). A meta-analysis of nine small randomized, placebo-controlled trials found that supplementation with soy isoflavones (50 to 99 mg/day; isolated or from isoflavone-containing soy protein) for a median eight-week period significantly increased brachial FMD, especially in postmenopausal women with low FMD levels (102). A more inclusive meta-analysis of 17 trials in either healthy individuals or in individuals with hyperlipidemia showed an increase of FMD with the intake of isolated isoflavones but not of isoflavones-containing soy protein (103).

Arterial stiffness or impaired arterial distensibility, another marker of vascular damage and an indicator of cardiovascular disease risk, is generally assessed using measures of aortic pulse-wave velocity (PWV) (104). Some, but not all, placebo-controlled clinical trials have suggested that supplementation with isoflavone-containing soy protein or isoflavone extracts might significantly decrease arterial stiffness (105-107). A recent randomized, double-blind, placebo-controlled study found that carotid-femoral PWV could be significantly reduced 24 hours after a single oral intake of 80 mg of soy isoflavones but only in participants able to produce equol (3). Long-term interventions are needed to evaluate the clinical relevance of such a result.

Finally, whether whole soy or isoflavones reduce the burden of subclinical atherosclerosis (99, 108) and lower blood pressure (109) in individuals at high CVD risk requires further examination.

Cognitive decline

Scientific research on the effect of soy isoflavones on cognitive function has been recently reviewed by Soni et al. (110). An observational study — the Honolulu-Asia Asian Study — that examined the relationship between soy intake and cognitive function found that Hawaiian men who reported consuming tofu (non-fermented soy product) at least twice weekly during midlife were more likely to have poor cognitive test scores 20 to 25 years later than those who reported consuming tofu less than twice a week (111). In an Indonesian study of elderly men and women, consumption of tofu was associated with worse memory, while consumption of tempeh (fermented soy) was associated with improved memory (112). In the multicenter, prospective, SWAN phytoestrogen ancillary study, the highest versus lowest tertile of isoflavone intakes was found to be associated with better scores in the processing speed test but worse scores in the verbal memory test in late perimenopausal and postmenopausal Asian women (79).

The results of several randomized controlled trials have been mixed. In a review of 12 trials, only half reported an improvement in cognitive function with soy isoflavone supplementation (110). Postmenopausal women given soy extracts, providing 60 mg/day of soy isoflavones for 6 to 12 weeks, performed better on cognitive tests of picture recall (short-term memory), learning rule reversals (mental flexibility), and a planning task compared to women given a placebo (113, 114). In a longer trial, postmenopausal women given supplements that provided 110 mg/day of soy isoflavones for six months performed better on a test of verbal fluency than women given placebos (115). In a cross-over trial lasting six months, women receiving 60 mg/day of soy isoflavones experienced significant improvements in cognitive performance and overall mood compared to when the women were given a placebo (116). However, in larger placebo-controlled trials, 80 mg/day of isoflavones for six months (117) or 99 mg/day of isoflavones for one year (118) did not affect performance on a battery of cognitive function tests, including tests for memory, attention, verbal fluency, motor control, and dementia in postmenopausal women. In addition, in the 30-month Women's Isoflavone Soy Health trial in 313 postmenopausal women, daily supplementation with 91 mg of soy isoflavones significantly improved visual memory but failed to improve other aspects of cognition or global cognition (119). Nevertheless, a recent meta-analysis of 10 randomized controlled trials found a significant improvement in the pooled summary of cognitive function tests in healthy postmenopausal women supplemented with 60 to 160 mg/day of soy isoflavones for 6 to 30 months (120).

There has been little investigation regarding the potential effects of soy isoflavones in individuals with cognitive impairments (121).

Disease Treatment

Menopausal symptoms

Menopause-related vasomotor symptoms, including hot flashes (flushes) and night sweats, affect over 75% of middle-aged US women (122). Concern over potential adverse effects of hormone replacement therapy (123, 124) has led to an increased interest in the use of phytoestrogen supplements in the management of menopausal symptoms (125).

To date, the effects of increasing soy isoflavone intake on the frequency and severity of menopausal symptoms have been examined in over 60 randomized controlled trials of small sample size (126). The results of these trials have been mixed, as reflected by the conclusions of several systematic reviews and meta-analyses published in the last decade (125, 127-134). However, a systematic Cochrane review published in 2013 concluded that supplements containing primarily genistein (four studies; 30 to 60 mg/day for 12 weeks to one year) — but not dietary soy (13 studies), soy isoflavone extracts (12 studies), or red clover extracts (nine studies) — significantly reduced the frequency of hot flashes (131). This result was consistent with previous analyses reporting alleviation of hot flashes in higher- rather than lower-genistein supplementation trials (126, 133, 134). Nevertheless, in a meta-analysis by Taku et al. (133), supplemental soy isoflavone extract (30 to 80 mg/day for six weeks to one year) was found to result in a net 17.4% reduction in hot flash frequency in 13 placebo-controlled trials (1,196 women). In addition, the meta-analysis of nine trials (988 women) showed a 30.5% reduction in hot flash severity with soy isoflavone extracts (30 to 135 mg/day for 12 weeks to one year) (133). Moreover, the observation that longer trials showed a greater efficacy of soy isoflavones was confirmed in a recent model-based meta-analysis by Li et al. (135). In this analysis of 16 studies, the authors estimated that supplementation with soy isoflavones required 48 weeks of treatment, compared to only 12 weeks for estradiol, in order to achieve close to 80% of its maximum effect (135). Besides, the maximum effect of soy isoflavones was found to account for only 57% of the maximum effect of estradiol (135).

Evidence from observational studies suggested that one's ability to produce equol might contribute to reducing the occurrence or severity of menopausal symptoms in postmenopausal women (see Metabolism and Bioavailability) (136, 137). Several relatively small intervention studies have examined the potential of equol to relieve these symptoms (reviewed in 138). A recent study in Chinese postmenopausal and equol-producing women showed no benefits of daily supplementation with soy flour (40 g) or daidzein (63 mg) for six months on the frequency or severity of menopausal symptoms (139). Yet, an earlier randomized controlled study found that, compared to equol non-producing women, those able to produce equol experienced improvements in menopausal symptoms like hot flashes following soy isoflavone supplementation (135 mg/day) for six months (140). In addition, the 12-week administration of 10 mg/day of equol to equol non-producing Japanese women experiencing three or more daily hot flashes significantly reduced the frequency and severity of hot flashes and neck and shoulder muscle stiffness compared to a placebo (141). In another study, daily supplementation with soy isoflavone (containing 24 mg of daidzein and 22 mg of genistein) or equol (10, 20, or 40 mg) supplements over an eight-week period resulted in equivalent reductions of the frequency of hot flashes in postmenopausal women with five or more daily hot flashes; however, 20 mg/day and 40 mg/day of equol supplements proved to be more effective than soy isoflavone supplements in the subgroup of women experiencing eight or more hot flashes per day (142). Nevertheless, because this study lacked an inert placebo control group, the results should be viewed with caution.

At present, supplements containing sufficient amounts of genistein may help alleviate vasomotor symptoms in women transitioning through menopause (126, 143).

Sources

Food sources

Isoflavones are found in small amounts in a number of legumes, grains, and vegetables, but soybeans are by far the most concentrated source of isoflavones in the human diet (144, 145). Average dietary isoflavone intakes in Japan, China, and other Asian countries range from 25 to 50 mg/day (20). Dietary isoflavone intakes are considerably lower in Western countries. Twenty-four-hour dietary recall data collected from 36,037 individuals in 10 countries (participating in the EPIC study) showed average isoflavone intakes to be lower than 1 mg/day (146). Compared to other European countries, the isoflavone intake was slightly higher in the British general population (2.3 mg/day) and health-conscious cohort (19.4 mg/day) (146).

Traditional Asian foods made from soybeans include tofu, tempeh, miso, and natto. Edamame refers to varieties of soybeans that are harvested and eaten in their green phase. Soy products that are gaining popularity in Western countries include soy-based meat substitutes, soy milk, soy cheese, and soy yogurt. The isoflavone content of a soy protein isolate depends on the method used to isolate it. Soy protein isolates prepared by an ethanol wash process generally lose most of their associated isoflavones, while those prepared by aqueous wash processes tend to retain them (147). Some foods that are rich in soy isoflavones are listed in **Table 1**, along with their isoflavone content. Because the isoflavone content of soy foods can vary considerably among brands and among different lots of the same brand (147), these values should be viewed only as a guide. Given the potential health implications of diets rich in soy isoflavones, accurate and consistent labeling of the soy isoflavone content of soy foods is needed. Of note, foods of animal origin also contain low levels of isoflavones (and other phytoestrogens), derived from animal feeds and pastures (148). More information on the isoflavone content of foods is available from the USDA Food Composition Database website and the USDA Database for the Isoflavone Content of Selected Foods report (149).

Table 1. Total Isoflavone, Daidzein, Genistein, and Glycitein Content of Selected Foods*

Food	Serving	Total Isoflavones (mg)	Daidzein (mg)	Genistein (mg)	Glycitein (mg)
Soy protein concentrate, aqueous washed	3.5 oz	94.6	38.2	52.8	4.9
Soy protein concentrate, alcohol washed	3.5 oz	11.5	5.8	5.3	1.5
Miso	½ cup	57	22.6	32	4.1
Soybeans, mature seeds, boiled	½ cup	56	26.5	26.9	3.2
Tempeh	3 ounces	51.5	19.3	30.7	3.2
Tempeh, cooked	3 ounces	30.3	11.1	18	1.2
Soybeans, dry roasted	1 ounce	41.6	17.4	21.2	3.7
Soy milk, low-fat	1 cup	6.2	2.4	3.7	0.1
Tofu yogurt	½ cup	21.3	7.5	12.3	1.6
Tofu, soft	3 ounces	19.2	8.1	10.1	1.4
Soybeans, green, boiled (Edamame)	½ cup	16.1	6.7	6.3	4.1
Meatless (soy) burger, unprepared	1 patty	4.5	1.6	3.5	0.4
Meatless (soy) sausage	3 links	10.8	3.3	6.9	1.7
Soy cheese, cheddar	1 oz	1.9	0.5	0.6	0.8

*Isoflavone content of soy foods can vary considerably between brands and between different lots of the same brand (147); therefore, these values should be viewed only as a guide.

Supplements

Soy isoflavone extracts and supplements are available as dietary supplements without a prescription in the US. These products are not standardized, and the amounts of soy isoflavones they provide may vary considerably. Moreover, quality control may be an issue with some of these products (150). When isoflavone supplements available in the US were tested for their isoflavone content by an independent laboratory, the isoflavone content in the product differed by more than 10% from the amount claimed on the label in approximately 50% of the products tested (151).

Infant formulas

Soy protein-based infant formulas are made from soy protein isolate and contain significant amounts of soy isoflavones (**Table 2**). In 1997, the total isoflavone content of soy-based infant formulas that were commercially available in the US ranged from 32 to 47 mg/liter (~34 fluid ounces) (152).

Table 2. Total Isoflavone, Daidzein, Genistein, and Glycitein Content of Selected Soy-based Infant Formulas

Soy-based Formula	Serving	Total Isoflavones (mg)	Daidzein (mg)	Genistein (mg)	Glycitein (mg)
Mead Johnson Prosobee, ready to feed	8 fl oz.	9.4	4.1	5.3	—
Abbott Nutrition, Similac, Isomil, ready to feed	8 fl oz.	5.4	1.8	3.3	0.3
PBM products, soy, ready to feed (formerly Wyeth-Ayerst)	8 fl oz.	6.4	1.8	3.9	0.7

Safety

Soy isoflavones have been consumed by humans as part of soy-based diets for many years without any evidence of adverse effects (145). The 75th percentile of dietary isoflavone intake has been reported to be as high as 65 mg/day in some Asian populations (153). Although diets rich in soy or soy-containing products appear safe and potentially beneficial, the long-term safety of very high supplemental doses of soy isoflavones is not yet known. One study in older men and women found that 100 mg/day of soy isoflavones for six months was well tolerated (154). Yet, longer-term studies are needed to evaluate the safety of isoflavones.

Adverse effects

Safety for breast cancer survivors

The safety of high intakes of soy isoflavones and other phytoestrogens for breast cancer survivors is an area of concern among scientists and clinicians. The results of cell culture and animal studies have been conflicting; some preclinical studies showed that soy isoflavones might stimulate the growth of estrogen receptor-positive (ER+) breast cancer cells (155, 156), while others suggested that they might either potentiate (157, 158) or abrogate the anticancer effects of tamoxifen on breast tissue (159, 160).

Very limited data from clinical trials suggested that increased consumption of soy isoflavones (38 to 45 mg/day) may show weak estrogenic effects in human breast tissue (161, 162). However, a study in women with biopsy-confirmed breast cancer found that supplementation with 200 mg/day of soy isoflavones did not increase breast cell proliferation — a marker of breast cancer risk — over the two to six weeks before surgery when compared to a control group that did not take soy isoflavones (163). A few large prospective cohort studies have examined the association between soy isoflavone intake and breast cancer recurrence and survival. In the Shanghai Breast Cancer Survival Study that followed 5,042 female breast cancer survivors for a median of 3.9 years, consumption of isoflavone-rich soy foods was significantly associated with a 29% lower risk of death and a 32% lower risk of cancer recurrence (164). In this study, soy isoflavone intake was associated with a significant 23% reduced risk of cancer recurrence and a nonsignificant 21% reduced risk of death (164). A pooled analysis of data from 9,514 breast cancer survivors from the Shanghai Breast Cancer Survival Study (164), the Life After Cancer Epidemiology study (165), and the Women's Healthy Eating and Living study (166) found a 25% reduced risk of recurrence with soy isoflavone intakes ≥10 mg/day (compared to intakes of <4 mg/day) (167). A subgroup analysis showed that the inverse association between soy isoflavone intake and recurrence was significant only among women taking the anticancer drug, tamoxifen. No inverse association was reported between soy isoflavone intake and the risks of all-cause and breast cancer-specific mortality (167).

Given the available data, some experts think that women with a history of breast cancer, particularly ER+ breast cancer, should not increase their consumption of phytoestrogens, including soy isoflavones (168). Nevertheless, there is not enough evidence to discourage breast cancer survivors from consuming soy foods in moderation (143, 169).

Safety of soy protein-based infant formulas

Infant formula made from soy protein isolate has been commercially available since the mid-1960s (170). As much as 25% of the infant formula sold in the US is soy protein-based formula (171). The American Academy of Pediatrics (AAP) supports the use of soy protein isolate-based formula for normal growth and development of term infants whose needs are not being met by human milk or cow's milk-based formulas (171). Soy protein-based formulas are especially indicated for infants with galactosemia and hereditary lactase deficiency, but they have no proven value in the prevention or management of infantile colic and fussiness (171).

Since infants fed soy-based formulas are exposed to relatively high levels of isoflavones (152), which they can absorb and metabolize, concern has been raised regarding potential long-term effects on anthropometric growth, bone health, as well as reproductive, endocrine, and immune functions (152, 172). In addition to the AAP review (171), a recent systematic review and meta-analysis of data published between 1909 and 2013 found no clinical concerns regarding nutritional adequacy, sexual development, thyroid disease, immune function, and neurodevelopment in infants fed soy protein-fed formulas (173). Specifically, this review identified 14 clinical trials comparing infants fed soy-based formula with infants fed human milk or cow's milk-based formula and found that soy-based formula adequately supported growth and development in the first year of life (173). In addition, the results of three observational studies suggested no adverse effects of soy protein-based formula on the neurodevelopment of children (174-176). Two of these observational studies of low-to-moderate quality also reported associations between soy protein-based formula intake and marginal adverse events, including early menarche (176, 177) and increased duration of menstrual bleeding (176). A recent prospective cohort study (the Beginnings study) examining the effects of early infant feeding on reproductive organ development during childhood found no differences in the volume and structure of the reproductive organs of 101 five-year-old boys and girls who were either breastfed or fed soy protein- or cow's milk-based formula as infants (178). Finally, no adverse health effects have been associated with the presence of phytates and aluminum in soy protein-based formulas fed to full-term infants (reviewed in 173).

At present, there is no convincing evidence that infants fed soy protein-based formula are at greater risk for adverse effects than infants fed cow's milk-based formula. Nonetheless, if current evidence shows a safety profile for use of soy protein-based formulas in term infants, they are not designed or recommended for preterm infants (171). Also, recent preliminary findings suggesting potential links between consumption of soy protein-based formulas and adverse effects in autistic children deserve further investigation (179, 180).

Male reproductive health

Claims that soy food/isoflavone consumption can have adverse effects on male reproductive function, including feminization, erectile dysfunction, and infertility, are primarily based on animal studies and case reports (181). Exposure to isoflavones (including at levels above typical Asian dietary intakes) has not been shown to affect either the concentrations of estrogen and testosterone, or the quality of sperm and semen (181, 182). Thorough reviews of the literature found no basis for concern but emphasized the need for long-term, large scale comprehensive human studies (181, 183).

Thyroid function

In cell culture and animal studies, soy isoflavones have been found to inhibit the activity of thyroid peroxidase, an enzyme required for thyroid hormone synthesis (184, 185). However, high intakes of soy isoflavones do not appear to increase the risk of hypothyroidism as long as dietary iodine consumption is adequate (186). Since the addition of iodine to soy-based formulas in the 1960s, there have been no further reports of hypothyroidism in soy formula-fed infants (187). Several clinical trials, mostly in women with sufficient iodine intakes, have not found increased consumption of soy isoflavones to result in clinically significant changes in circulating thyroid hormone concentrations (188-192).

Pregnancy

To date, studies have not examined the effect of an isoflavone-rich diet on fetal development or pregnancy outcomes in humans, and the safety of isoflavone supplements during pregnancy has not been established.

Drug interactions

Fermented soy foods contain highly variable amounts of the biologically active amine, tyramine, which is catabolized in the body by monoamine oxidase enzyme (MAO) and excreted in the urine. The ingestion of very high amount of tyramine may saturate the detoxification system and lead to clinical symptoms of intoxication. Because individuals taking MAO inhibitors (MAOIs; phenelzine, tranylcypromine) are at greater risk of adverse effects, they should avoid consuming fermented soy products (193, 194). Because colonic bacteria play an important role in the metabolism of soy isoflavones, antibiotic therapy could decrease their biological activity (193). Some evidence from animal studies suggested that high intakes of soy isoflavones, particularly genistein, could interfere with the antitumor effects of tamoxifen (Nolvadex) (159). Yet, a recent pooled analysis of three prospective cohort studies found that the risk of recurrence in breast cancer survivors was reduced to a greater extent with soy isoflavone intake in tamoxifen users than in nonusers (see Safety for breast cancer survivors) (167). Nonetheless, until more is known about potential interactions in humans, those taking tamoxifen or other selective estrogen receptor modulators (SERMs) to treat or prevent breast cancer should be cautious and seek medical advice regarding the use of soy protein supplements or isoflavone extracts (193).

High intakes of soy protein may interfere with the efficacy of the anticoagulant medication warfarin. There is one case report of an individual on warfarin who developed subtherapeutic international normalized ratio (INR; prothrombin time) values upon consuming ~16 ounces of soy milk daily for four weeks (195). INR values returned to therapeutic levels two weeks after discontinuing soy milk.

The amount of levothyroxine required for adequate thyroid hormone replacement has been found to increase in infants with congenital hypothyroidism fed soy formula (187, 196). Taking levothyroxine at the same time as a soy protein supplement also increased the levothyroxine dose required for adequate thyroid hormone replacement in an adult with hypothyroidism (197).

Regular consumption of a diet high in soy — rather than supplementation with isoflavone extracts or isoflavone containing isolated soy protein — may help lower fasting glucose concentrations (198). It is unknown whether individuals taking antidiabetic agents might be at risk of hypoglycemia if they follow a soy-based meal replacement plan rather than a diet plan recommended by the American Diabetes Association (199).

Summary

- Chlorophyll a and chlorophyll b are natural, fat-soluble chlorophylls found in plants. *(More information)*
- Sodium copper chlorophyllin (SCC) is a semi-synthetic mixture of water-soluble sodium copper salts derived from chlorophyll. *(More information)*
- SCC has been used orally as an internal deodorant and topically in the treatment of slow-healing wounds for more than 50 years without any serious side effects. *(More information)*
- Chlorophylls and SCC form tight molecular complexes with some chemicals known or suspected to cause cancer, and in doing so, may block carcinogenic effects. Carefully controlled studies have not been undertaken to determine whether a similar mechanism might limit uptake of required nutrients. *(More information)*
- Supplementation with SCC before meals substantially decreased a urinary biomarker of aflatoxin-induced DNA damage in a Chinese population at high risk of liver cancer due to unavoidable, dietary aflatoxin exposure from moldy grains and legumes. *(More information)*
- Scientists are hopeful that SCC supplementation will be helpful in decreasing the risk of liver cancer in high-risk populations with unavoidable, dietary aflatoxin exposure. However, it is not yet known whether SCC or natural chlorophylls will be useful in the prevention of cancers in people who are not exposed to significant levels of dietary aflatoxin. *(More information)*

Introduction

Chlorophyll is the pigment that gives plants and algae their green color. Plants use chlorophyll to trap light needed for photosynthesis (1). The basic structure of chlorophyll is a porphyrin ring similar to that of heme in hemoglobin, although the central atom in chlorophyll is magnesium instead of iron. The long hydrocarbon (phytol) tail attached to the porphyrin ring makes chlorophyll fat-soluble and insoluble in water. Chlorophyll a and chlorophyll b represent about 99% of the chlorophyll species found in edible plants (**Figure 1**; 2), while some algae and microalgae contain minor quantities of chlorophyll c pigments (e.g., *Laminaria ochroleuca*, *Undaria pinnatifida*) (3). Chlorophyll a and b only have a small difference in one of the side chains but an intact phytol tail, while the common characteristic of chlorophyll c isoforms is the absence of a phytol tail. These structural differences cause each type of chlorophyll to absorb light at slightly different wavelengths.

Metallo-chlorophyll derivatives, including chlorophyllins, can be chemically synthesized or produced in industrial food processing; these compounds contain zinc, iron, or copper in place of the central magnesium atom (2). The most studied chlorophyllin, sodium copper chlorophyllin (SCC), is a semi-synthetic mixture of sodium copper salts derived from chlorophyll (4, 5). SCC is often simply called 'chlorophyllin' in the older scientific literature, with newer publications specifying whether iron, zinc, copper, or magnesium chlorophyllin were studied. During its synthesis, the magnesium atom at the center of the ring is replaced with copper (or other metals), and the phytol tail is lost. Unlike natural chlorophyll, chlorophyllins (regardless of the metal used) are water-soluble. Although the content of different SCC mixtures may vary, two compounds commonly found in commercial SCC are trisodium copper chlorin e$_6$ and disodium copper chlorin e$_4$ (**Figure 2**).

Metabolism and Bioavailability

Little is known about the bioavailability and metabolism of chlorophyll in humans, although it is known that chlorophyll undergoes extensive metabolism once consumed. Animal model studies show only about 1%-3% of chlorophyll is absorbed, while the rest is excreted in the feces, primarily as pheopytin and pyropheophytin metabolites, indicating that significant transformation and microbial metabolism occur in the gastrointestinal tract (reviewed in 2). A recent study in eight healthy adults found pheophytin and pheophorbide derivatives in the blood of most subjects following consumption of 1.2 kg boiled spinach, a concentrated source of chlorophyll (6).

Sodium copper chlorophyllin was originally thought to be poorly absorbed because of its lack of apparent toxicity. However, a placebo-controlled clinical trial found that significant amounts of copper chlorin e$_4$ in the serum of people taking chlorophyllin tablets (300 mg/day) (7), indicating that it is indeed absorbed. *In vitro* studies have found chlorin e$_4$ to have a higher stability than chlorin e$_6$ (2).

More research, however, is needed to understand the bioavailability and metabolism of natural chlorophylls and chlorin compounds in synthetic chlorophyllin.

Biological Activities

Complex formation with other molecules

Chlorophyll and sodium copper chlorophyllin are able to form tight molecular complexes with certain chemicals known or suspected to cause cancer, including polyaromatic hydrocarbons found in tobacco smoke (8), some heterocyclic amines found in cooked meat (9), and aflatoxin-B$_1$ (10). The binding of chlorophyll or SCC to these potential carcinogens may interfere with gastrointestinal absorption of potential carcinogens, reducing the amount that reaches susceptible tissues (11). This has been demonstrated in humans: a cross-over study in three volunteers that used accelerator mass spectrometry to study the pharmacokinetics of an ultra-low dose of aflatoxin-B$_1$ found a 150-mg dose of either SCC or chlorophyll could decrease absorption of aflatoxin-B$_1$ (12).

Antioxidant effects

SCC can neutralize several physically relevant oxidants *in vitro* (13-16), and limited data from animal studies suggest that SCC supplementation may decrease oxidative damage induced by chemical carcinogens and radiation (17, 18). While chlorophyll and its derivatives have demonstrated antioxidant activity in *in vitro* assays (15, 19), the relevance of these findings to humans is not clear.

Modification of the metabolism and detoxification of carcinogens

To initiate the development of cancer, some chemicals (procarcinogens) must first be metabolized to active carcinogens that are capable of damaging DNA or other critical molecules in susceptible tissues. Since enzymes in the cytochrome P450 family are required for the activation of some procarcinogens, inhibition of cytochrome P450 enzymes may decrease the risk of some types of chemically induced cancers. *In vitro* studies indicate that SCC may decrease the activity of cytochrome P450 enzymes (8, 20, 21). Phase II biotransformation enzymes promote the elimination of potentially harmful toxins and carcinogens from the body. Limited data from animal studies indicate that SCC may increase the activity of the phase II enzyme quinone reductase (22).

Therapeutic effects

One *in vitro* study showed that human colon cancer cells undergo cell cycle arrest after treatment with SCC (23). The mechanism involved inhibition of ribonucleotide reductase activity. Ribonucleotide reductase plays a pivotal role in DNA synthesis and repair and is a target of currently used cancer therapeutic agents, such as hydroxyurea (23). While this may provide a potential avenue for SCC in the clinical setting, sensitizing cancer cells to DNA damaging agents, *in vivo* studies are needed.

Metal absorption

The porphyrin structure of chlorophyll is analogous to the heme structure found in blood and muscle tissue. Because heme-bound iron has higher bioavailability than nonheme iron (the most common form of iron in plant-based sources, e.g., legumes, spinach), iron uptake from iron chlorophyll is of interest. Toxicity studies in rats suggest iron chlorophyllin is generally safe for mammalian consumption (24). *In vitro* studies demonstrate that iron chlorophyllin is as good as heme in delivering iron to intestinal cells, and significantly better than the most common supplemental form of iron (i.e., ferrous sulfate) when incorporated into most food matrices (25). However, work in this area is nascent and has not yet been validated in humans. It is also not known if metallo-chlorophyll derivatives of copper or zinc increase absorption of these essential divalent metals.

Disease Prevention

Aflatoxin-associated liver cancer

Aflatoxin-B$_1$ (AFB$_1$), a liver carcinogen produced by certain species of fungus, is found in moldy grains and legumes, including corn, peanuts, and soybeans (4, 11). In hot, humid regions of Africa and Asia with improper grain storage facilities, high levels of dietary AFB$_1$ are associated with increased risk of hepatocellular carcinoma. Moreover, the combination of hepatitis B infection and high dietary AFB$_1$ exposure increases the risk of hepatocellular carcinoma still further. In the liver, AFB$_1$ is metabolized to a carcinogen capable of binding DNA and causing mutations. In animal models of AFB$_1$-induced liver cancer, administration of SCC at the same time as dietary AFB$_1$ exposure significantly reduces AFB$_1$-induced DNA damage in the livers of rainbow trout and rats (26-28) and dose-dependently inhibits the development of liver cancer in trout (29). Likewise, natural chlorophyll has also been found to inhibit AFB$_1$-induced liver cancer in the rat (28). Collectively, this evidence supports a role for SCC and/or chlorophyll itself in limiting cancer initiation. In contrast, data suggest a limited role for SCC in influencing cancer progression. For example, one rat study found that SCC did not protect against aflatoxin-induced liver damage when given after tumor initiation (30).

Because of the long time period between AFB$_1$ exposure and the development of cancer in humans, an intervention trial might require as long as 20 years to determine whether SCC supplementation can reduce the incidence of hepatocellular carcinoma in people exposed to high levels of dietary AFB$_1$. However, a biomarker of AFB$_1$-induced DNA damage (AFB$_1$-N^7-guanine) can be measured in the urine, and high urinary levels of AFB$_1$-N^7-guanine have been associated with significantly increased risk of developing hepatocellular carcinoma (31). In order to determine whether chlorophyllin could decrease AFB$_1$-induced DNA damage in humans, a randomized, placebo-controlled intervention trial was conducted in 180 adults residing in a region in China where the risk of hepatocellular carcinoma is very high due to unavoidable, dietary AFB$_1$ exposure and a high prevalence of chronic hepatitis B infection (32). Participants took either 100 mg of SCC or a placebo before meals three times daily. After 16 weeks of treatment, urinary levels of AFB$_1$-N^7-guanine were 55% lower in those taking SCC than in those taking the placebo, suggesting that SCC supplementation before meals can substantially decrease AFB$_1$-induced DNA damage. Although a reduction in hepatocellular carcinoma has not yet been demonstrated in humans taking SCC, scientists are hopeful that supplementation will provide some protection to high-risk populations with unavoidable, dietary AFB$_1$ exposure (11).

It is not known whether SCC will be useful in the prevention of cancers in people who are not exposed to significant levels of dietary AFB$_1$, as is the case for most people living in the US. Many questions remain to be answered regarding the exact mechanisms of cancer prevention by SCC, the implications for the prevention of other types of cancer, and the potential for natural chlorophylls in the diet to provide cancer protection.

Therapeutic Uses of Chlorophyllin

Internal deodorant

Observations in the 1940s and 1950s that topical SCC had deodorizing effects on foul-smelling wounds led clinicians to administer SCC orally to patients with colostomies and ileostomies in order to control fecal odor (33). While early case reports indicated that SCC doses of 100 to 200 mg/day were effective in reducing fecal odor in ostomy patients (34, 35), a placebo-controlled trial found that 75 mg of oral SCC three times daily was no more effective than placebo in decreasing fecal odor assessed by colostomy patients (36). Several case reports have been published indicating that oral SCC (100-300 mg/day) decreased subjective assessments of urinary and fecal odor in incontinent patients (33, 37).

Trimethylaminuria is a hereditary disorder characterized by the excretion of trimethylamine, a compound with a "fishy" or foul odor. One study in a small number of Japanese patients with trimethylaminuria found that oral SCC (60 mg three times daily) for three weeks significantly decreased urinary trimethylamine concentrations (38).

Wound healing

Research in the 1940s indicated that chlorophyllin slowed the growth of certain anaerobic bacteria in the test tube and accelerated the healing of experimental wounds in animals. These findings led to the use of topical SCC solutions and ointments in the treatment of persistent open wounds in humans (39). During the late 1940s and 1950s, a series of largely uncontrolled studies in patients with slow-healing wounds, such as vascular ulcers and pressure (decubitus) ulcers, reported that the application of topical SCC promoted healing more effectively than other commonly used treatments (40, 41). In the late 1950s, SCC was added to papain and urea-containing ointments used for the chemical debridement of wounds in order to reduce local inflammation, promote healing, and control odor (33). SCC-containing papain/urea ointments are still available in the US by prescription (42). Several studies have reported that such ointments are effective in wound healing (43). A spray formulation of the papain/urea/SCC therapy is also available (44).

Skin conditions

A few small studies have investigated SCC as a topical treatment for various skin conditions. In a pilot study of 10 adults (ages 18-30 years) who had mild-to-moderate acne vulgaris and enlarged facial pores, twice daily application of a 0.1% liposomal SCC gel for three weeks improved a number of clinical parameters of the Global Acne Assessment Scale (i.e., facial oiliness, facial blotchiness, presence and size of facial pores, and number of acne lesions) compared to baseline (45). Additionally, a pilot study in 10 women (ages 40 years or older) with noticeable photodamage and solar lentigines found that twice daily topical application of a gel containing 0.66% SCC complex salts for eight weeks improved various clinical measures, including tactile and visual roughness of facial skin, skin radiance, fine lines, pore size, and overall photodamage (46). A few case reports have also observed some improvement in facial redness and rosacea with application of topical SCC (47).

While the reports from these studies are interesting, placebo-controlled clinical trials are needed to determine whether SCC may have utility in treating various skin conditions.

Sources

Chlorophylls

Chlorophylls are the most abundant pigments in plants, with chlorophyll a being two to four times as prevalent as chlorophyll b (6, 48). Dark-green leafy vegetables like spinach are rich sources of natural chlorophylls. The chlorophyll content of selected vegetables are presented in **Table 1** (49).

Table 1. Chlorophyll Content of Selected Raw Vegetables

Food	Serving	Chlorophyll (mg)
Spinach	1 cup	23.7
Parsley	½ cup	19.0
Cress, garden	1 cup	15.6
Green beans	1 cup	8.3
Arugula	1 cup	8.2
Leeks	1 cup	7.7
Endive	1 cup	5.2
Sugar peas	1 cup	4.8
Chinese cabbage	1 cup	4.1

Food and supplements

Chlorophyll

Green algae like chlorella are often marketed as supplemental sources of chlorophyll. Because natural chlorophyll is not as stable as SCC and is much more expensive, most over-the-counter chlorophyll supplements actually contain sodium copper chlorophyllin.

Sodium copper chlorophyllin

Oral preparations of sodium copper chlorophyllin (also called chlorophyllin copper complex) are available as a dietary supplement and as an over-the-counter drug (Derifil) used to reduce odor from colostomies and ileostomies, or to reduce fecal odor due to incontinence (50). Oral doses of 100 to 300 mg/day in three divided doses have been used to control fecal and urinary odor (see Therapeutic Uses of Chlorophyllin).

In the US, SCC is found in minor quantities in some types of green table olives (51). It is also approved for use as a green color additive in a limited number of foods like chewing gum (52), as well as in drugs and cosmetics, as detailed in the Code of Federal Regulations 21 (53).

Zinc chlorophyll derivatives

In US supermarkets, canned green beans thermally processed in a zinc chloride solution to produce zinc chlorophyll derivatives within the green beans themselves are sold under the trademarked name "veri-green" (54). Because zinc chlorophyll derivatives are more robust to heat and acid treatment, they better retain a bright green color as compared to native magnesium-bound chlorophyll (48).

Safety

Natural chlorophylls are not known to be toxic, and no toxic effects have been attributed to chlorophyllin despite more than 50 years of clinical use in humans (11, 33, 39). When taken orally, supplemental chlorophyll or sodium copper chlorophyllin may cause green discoloration of urine or feces, or yellow or black discoloration of the tongue (55). There have also been occasional reports of diarrhea related to oral SCC use. When applied topically to wounds, SCC has been reported to cause mild burning or itching in some cases (56). Oral chlorophyllin may result in false positive results on guaiac card tests for occult blood (57). Since the safety of chlorophyll or chlorophyllin supplements has not been tested in pregnant or lactating women, they should be avoided during pregnancy and lactation.

Food and Beverages

Plant-based foods, including fruit, vegetables, legumes, whole grains, and nuts, are prominent features of healthy dietary patterns. In addition to providing energy and essential micronutrients, plant-based foods contribute thousands of biologically active phytochemicals (plant chemicals that may affect health) to the human diet. While there is ample evidence to support the health benefits of diets rich in fruit, vegetables, legumes, whole grains, and nuts, evidence that these effects are due to specific nutrients or phytochemicals is limited. Although scientists are very interested in the potential for specific phytochemicals to prevent or treat disease, current scientific evidence suggests that plant-based foods are the healthiest phytochemical delivery system.

Summary

- Dietary patterns characterized by high intakes of fruit and vegetables are consistently associated with lower risks of cardiovascular disease and type 2 diabetes mellitus. *(More information)*
- Although prospective cohort studies provide weak support for an association between total fruit and vegetable consumption and cancer risk, they provide some evidence that high intakes of certain classes of fruit or vegetables are associated with reduced risk of individual cancers. *(More information)*
- Most observational studies suggest that diets rich in fruit and vegetables may have beneficial effects on bone health during aging. Yet, large randomized controlled trials are needed to confirm such benefits. *(More information)*
- Adherence to diets rich in fruit and vegetables has been associated with a lower risk of age-related macular degeneration (AMD), a leading cause of blindness in older people. Randomized controlled trials found supplementation with carotenoids — compounds found in fruit and vegetables — may delay the progression to advanced AMD in subjects with the disease. *(More information)*
- Oxidative stress and inflammation play key roles in the etiology of chronic obstructive lung disease (COPD). Current evidence suggests that fruit and vegetables high in antioxidants like vitamin C, β-carotene, or flavonoids could play a protective role against COPD. *(More information)*
- Regular consumption of fruit and vegetables may reduce risk of some chronic diseases, thereby improving overall health and longevity. *(More information)*
- The 2015-2020 Dietary Guidelines for Americans recommend consuming a healthy diet that includes, among other things, a variety of vegetables from all of the subgroups and fruit. *(More information)*

Introduction

Despite disagreements regarding the optimal components of a healthy diet, the importance of fruit and vegetables is rather undisputed. The results of numerous epidemiological studies provide consistent evidence suggesting associations between diets rich in fruit and vegetables and lower risks of chronic disease. On the other hand, evidence that very high doses of individual micronutrients or phytochemicals found in fruit and vegetables can provide similar health benefits is inconsistent and relatively weak. In addition to essential micronutrients, fruit and vegetables contain thousands of biologically active phytochemicals that are likely to interact in a number of ways to prevent disease and promote health (1). Fruit and vegetables are rich in antioxidants, which help protect the body from oxidative damage induced by pro-oxidants. The best way to take advantage of these complex interactions is to eat a variety of fruit and vegetables.

Disease Prevention

Cardiovascular disease

Prospective cohort studies have consistently reported inverse associations between high intakes of fruit and vegetables and risk of cardiovascular disease (CVD), including coronary heart disease (CHD) and stroke (2-4). A 2017 meta-analysis of prospective cohort studies found a 16% lower risk of CVD with high versus low fruit and vegetable intake and an 8% lower risk with every 200 grams (g)/day increment in daily fruit and vegetable intake in a dose-response analysis (2). Similar risk reductions were reported for daily 200-g increments in fruit and/or vegetable intake and risks of CHD and stroke (2). However, regarding primary CVD prevention in high-risk subjects, evidence that increasing intakes of fruit and vegetable can improve cardiovascular risk factors is scarce because of a lack of long-term intervention studies (5). In a small 12-week intervention study in 109 overweight adults at high risk for CVD, no differences in blood pressure and serum concentrations of low-density lipoprotein (LDL)-cholesterol and C-reactive protein (CRP; a marker of inflammation) were found between participants consuming two (~160 g), four (~320 g), or seven (~560 g) daily servings of fruit and vegetables (6).

Nonetheless, adherence to the Dietary Approaches to Stop Hypertension (DASH) diet, which emphasizes fruit, vegetables, whole grains, poultry, fish, nuts, and low-fat dairy, was found to substantially lower systolic/diastolic blood pressures by 11.4/5.5 mm Hg in hypertensive and 3.5/2.1 mm Hg in normotensive people compared to a typical US diet (for additional information on the DASH diet, see the National Institutes of Health website) (7). Blood pressure lowering effectively reduces CVD risk (8). Adherence to a Mediterranean-style dietary pattern, also characterized by high fruit and vegetable intake, might further contribute to preventing cardiovascular events in healthy and high-risk subjects through normalizing total and LDL-cholesterol concentrations in the circulation (9).

A number of compounds may play a part in the cardioprotective effects of fruit and vegetables, including vitamin C, folate, potassium, fiber, and various phytochemicals (10, 11). However, supplementation with individual micronutrients or phytochemicals has not generally resulted in significantly decreased incidence of cardiovascular events in randomized controlled trials. Thus, in the case of fruit and vegetables, the benefit of the whole may be greater than the sum of its parts. Of note, the World Health Organization (WHO) recommends the daily consumption of >400 g of fruit and vegetables as part of a healthy diet low in fat, sugar, and salt (sodium chloride), in order to minimize the risk of certain non-communicable diseases like CVD and type 2 diabetes mellitus (12).

Type 2 diabetes mellitus

Nearly 10% of the US population is affected by type 2 diabetes mellitus and another 34% has impaired glucose control (prediabetes) that places them at high risk of developing type 2 diabetes (13). Adherence to a Mediterranean-style or Dietary Approaches to Stop Hypertension (DASH) diet — both rich in vegetables, legumes, fruit, and nuts — has been associated with a lower risk of developing type 2 diabetes (14). Yet, a recent meta-analysis of prospective cohort studies failed to find any association between intakes of vegetables, legumes, fruit, or nuts and the risk of type 2 diabetes (15). In contrast, high intakes of whole-grain and dairy foods were linked to a lower risk of type 2 diabetes, while consumption of sugar-sweetened beverages and red and processed meat were associated with an increased risk of diabetes (15). Whether evidence for a potential protective effect of fruit and vegetables regarding type 2 diabetes is more easily detectable when they are combined with other food groups within a diet rather than when their effect is singled out is unclear. A recent meta-analysis of 12 cross-sectional and two prospective cohort studies found a 27% lower risk of type 2 diabetes with the consumption of a vegetarian diet (16). Yet, it is unclear whether the potential benefit of such a diet is linked to the fact that it does not include foods that are associated with a higher diabetes risk (i.e., red and processed meat) and/or because of the inclusion of foods like fruit and vegetables that may be protective. Nevertheless, in the European Prospective Investigation into Cancer and nutrition (EPIC)-Norfolk, a prospective study that followed 3,704 participants for nearly 11 years, a lower risk of type 2 diabetes was linked to higher intakes of vegetables (but not fruit), as well as with a greater diversity of consumed fruit and vegetables (17). A dose-response analysis found an 8% lower risk of diabetes with every increase of two items added to the variety of fruit or vegetables consumed each week (17). A follow-up study also showed that a composite score reflecting fruit and vegetable consumption, derived from circulating concentrations of vitamin C, β-carotene, and lutein, was also inversely associated with the risk of type 2 diabetes in this cohort (18).

Without changes in lifestyle behavior, especially regarding dietary habits and physical activity, individuals with prediabetes will eventually progress to develop overt type 2 diabetes. Strategies promoting healthier eating habits to improve glucose control usually encourage the consumption of more fruit and vegetables and the concomitant reduction of sugar and fat intake. The American Diabetes Association does not specifically emphasize an increase in fruit and vegetable intake for diabetes prevention yet recommends dietary strategies that include reducing caloric and fat intake, as well as increasing intake of whole-grain foods and dietary fiber that can be sourced in fruit and vegetables (19).

Cancer

A plethora of observational studies has investigated the relationship between intakes of fruit and vegetables and risk of developing site-specific cancers. A 2014 report summarized the findings of 27 studies that examined fruit and vegetable consumption in relation to incidental cancer in participants of the ongoing, multicenter European Prospective Investigation into Cancer and nutrition (EPIC) study (20). This report found the highest versus lowest quintile of fruit intake (≥356 g/day vs. ≤89 g/day) to be associated with a 40% lower risk of oropharyngeal, laryngeal, and esophageal cancers and a 20% lower risk of lung cancer. No associations were observed between fruit intake and cancers of the lymphatic system, stomach, pancreas, breast, cervix, prostate, or bladder. There were also no inverse associations between intakes of vegetables and risk of cancer. More recently published EPIC data analyses also failed to find significant inverse associations between fruit and/or vegetable intakes and risk of hepatocellular carcinoma (21), colorectal cancer (22), hormone-receptor-positive breast cancer (23), or differentiated thyroid carcinoma (24). Further, mixed results from recent meta-analyses of observational studies are reported in **Table 1**, with significant associations noted in bold. Some of the discrepancies might be attributed to study design. Compared to prospective cohort studies, which collect dietary information from participants before they are diagnosed with cancer, retrospective case-control studies are more susceptible to bias in the selection of participants (cases and controls) and with dietary recall (25). For example, this might explain why fruit intake is associated with the risk of esophageal adenocarcinoma in the meta-analysis of six case-control studies but not in that of three cohort studies in the meta-analysis by Li et al. (26). Inaccurate measurements (introducing measurement bias) and changes in the diet during follow-up in prospective cohort studies may also contribute to reporting associations that are proven spurious or to missing true associations. A 2012 meta-analysis of prospective studies suggested that, when compared to direct measurements of plasma carotenoids, the use of a food-frequency questionnaire to assess carotenoid intake introduced measurements errors that led to underestimating the strength of the association between carotenoid intake and reduced breast cancer risk (27).

Table 1. Fruit & Vegetable Intake and Cancer Risk: Meta-analyses of Observational Studies

Type of Cancer	References	Highest versus Lowest Quantile of Intake	Type of Observational Studies	Risk Ratio [RR] or Odds Ratio [OR] (95% Confidence Interval)*
All cancer types	Aune et al. (2017) (2)	Total fruit & vegetables	14 prospective cohort studies	**RR: 0.97 (0.95-0.99)**
		Vegetables	19 prospective cohort studies	**RR: 0.96 (0.93-0.99)**

[#] Cohort, nested case-control, and case-cohort studies

Additional evidence from observational studies, discussed in MIC articles focusing specifically on cruciferous vegetables, garlic, carotenoid-rich vegetables, and legumes suggests that high intakes of certain classes of vegetables are associated with reduced risk of individual cancers. The 2007 report from the World Cancer Research Fund International (WCRF)/American Institute for Cancer Research (AICR) concluded that fruit and non-starchy vegetables were probably protective against some cancers, recommending a daily consumption of five portions (400 g; based on an average portion weighing 80 g) of a variety of vegetables and fruit (40). AICR continuously collates evidence from cohort and randomized controlled studies through its Continuous Update Project (CUP), and updated CUP-derived Cancer Prevention Recommendations are expected to be published in late 2017 (41).

Osteoporosis

Bone turnover

Fruit and vegetables are rich in precursors of bicarbonate ions (HCO$_3^-$), which serve to buffer acids in the body. When the quantity of bicarbonate ions is insufficient to maintain normal pH, the body is capable of mobilizing alkaline calcium salts from bone in order to neutralize acids consumed in the diet and generated by metabolism (42). It has been hypothesized that higher consumption of fruit and vegetables could help reduce the net acid content of the diet and preserve calcium in bones, which might otherwise be mobilized to maintain normal pH to the detriment of bone health. Results from the ancillary DASH-Sodium study, which emphasizes the intake of fruit, vegetables, whole-grain foods, and low-fat dairy, supported a beneficial link between bone health and fruit and vegetable intake. Compared to a control diet, one month-administration of the DASH diet to (pre)hypertensive middle-aged adults significantly lowered the rate of bone turnover, as shown by reduced serum concentrations of osteocalcin (OC), a marker of bone formation released by osteoblasts into circulation during the mineralization of newly synthesized collagen. C-terminal telopeptide of type 1 collagen (CTX) — a marker of bone resorption released from bone collagen into circulation following bone degradation by osteoclasts — was also decreased (43). However, more recent randomized controlled interventions found no effect of increasing fruit and vegetable intake on markers of bone turnover (44-46). The results of a placebo-controlled trial in 276 healthy postmenopausal women suggested that supplementing the diet with alkali, either through supplemental potassium citrate or an additional 300 g/day of fruit and vegetables, did not reduce bone turnover, increase bone mineral density (BMD), or blunt the age-associated bone loss over a two-year period (45). The effect of five portions of fruit and vegetables on measures of dietary acid/base balance and bone turnover markers was also reported as a secondary outcome in the Ageing and Dietary Intervention Trial that included 83 healthy older participants (ages, 65-85 years) (46). Compared to habitual fruit and vegetable intakes of ≤2 portions/day, the consumption of five portions per day for 16 weeks increased the alkalinity of the diet but failed to reduce markers of bone turnover (46). There were also no significant reductions in circulating bone turnover markers in postmenopausal women with osteopenia supplemented with six extra servings of fruit and vegetables per day (~400 g/day) for 12 weeks (44).

Bone mineral density

Several observational studies have examined intakes of fruit and vegetables in relation to bone mineral density (BMD) in men and women, providing mixed results (reviewed in 47). In an early cross-sectional analysis of the longitudinal Framingham Osteoporosis Study in elderly adults (mean age, 75 years), baseline intakes of fruit and vegetables were positively associated with BMD at various sites, including trochanter, femoral neck, and radius (48). Baseline fruit and vegetable intakes were also positively associated with longitudinal changes of trochanter BMD over four years in elderly men but not elderly women (48, 49). Two recent cross-sectional studies in Chinese cohorts reported positive relationships between BMD and intakes of fruit rather than vegetables (50, 51). In the cross-sectional analysis of two Hong-Kong-based cohorts of 3,995 older participants (≥65 years), higher daily intakes of fruit — but not vegetables — were associated with significantly higher whole-body and femoral neck BMD in men and women (50). The cross-sectional study of 3,089 Chinese adults (ages, 40-75 years) reported positive associations between whole-body, total hip, and femoral neck BMD and higher intakes of apples, pears, peaches, pineapples, plums, and to a lesser extent, citrus fruit (51). However, the two-year supplementation of 300 g/day of fruit and vegetables failed to reduce BMD loss in healthy postmenopausal women (45).

Risk of fracture

A pooled analysis of data from several prospective cohort studies, including the EPIC-Elderly Greece (9,534 participants), EPIC-Elderly Sweden (3,276 participants), Cohort of Swedish Men (COSM; 20,150 men), Swedish Mammography Cohort (SMC; 17,506 women), and Nurses' Health Study (NHS; 91,552 women), found a 39% higher risk of hip fracture with intakes of fruit and vegetables ≤1 serving/day compared to 4-5 daily servings (52). Further subgroup analysis linked higher hip fracture risk specifically with low intakes of vegetables rather than fruit. Finally, compared to 4-5 daily servings of fruit and vegetables, there was no reduction in hip fracture risk with intakes greater than 5 servings/day (52). The consumption of fruit and vegetables has been recently examined in relation to 415 fracture-related hospitalizations identified during a 14.5-year follow-up of 1,468 elderly participants (≥70 years) of the Perth Longitudinal Study of Aging in Women (PLSAW) (53). Whereas no association was found between fruit intakes and fracture risk, high versus low intake of total vegetables (≥3 servings/day versus <2 servings/day) was associated with a 27% reduced risk of all fractures and a 39% reduced risk of hip fractures. Further analyses suggested an inverse association between consumption of allium vegetables (onion, leek, and garlic) and risk of fracture (53).

Although observational studies suggest a positive relationship between diets rich in fruit and vegetables and bone health during aging, randomized controlled studies are needed to examine the nature of this association.

Eye diseases

Cataracts

Cataracts are thought to be caused by oxidative damage of proteins in the eye's lens induced by long-term exposure to ultraviolet (UV) light (54). The resulting cloudiness and discoloration of the lens leads to vision loss that becomes more severe with age. A 2015 meta-analysis of nine observational studies found a 28% lower risk of age-related cataracts with the highest versus lowest intakes of vegetables (55). In a large Swedish prospective study that followed 30,607 middle-aged and elderly women for a mean 7.7 years, the risk of age-related cataracts has been examined in relation to the estimated total antioxidant capacity of the diet (56). Higher versus lower estimates of total dietary antioxidant capacity were associated with a 13% lower risk of cataracts. Subgroup analyses showed that this inverse association was statistically significant in women younger than 65 years and in corticosteroid users (56). Pooled analyses of observational studies that investigated the relationships between individual nutrients with antioxidant properties and the risk of cataracts have also suggested a lower risk of cataracts with higher intakes or higher blood concentrations of vitamin C, vitamin A, or β-carotene, although the results vary according to study design (i.e., case-control versus cross-sectional versus longitudinal) (57, 58). However, a 2012 review of nine randomized clinical trials found no substantial effect of β-carotene, vitamin C, and vitamin E, administered individually or in combination over 2.1 to 12 years, on the risk of cataracts or cataract surgery (59). In addition, a large randomized controlled trial in 5,802 subjects at high risk for cardiovascular disease recently reported no difference in cataract surgery incidence over a seven-year follow-up period between participants assigned to a Mediterranean diet that included the whole range of antioxidant nutrients and those assigned to a control diet (60). A secondary analysis reported a 29% lower cataract surgery risk in participants in the highest versus lowest tertile of vitamin K$_1$ intake (61).

Age-related macular degeneration

In industrialized countries, degeneration of the macula, located in the center of the retina, is the leading cause of blindness in older adults (62). Long-term light exposure and oxidative damage in the outer segments of photoreceptors may lead to drusen and/or pigment abnormalities in the macula, increasing the risk of age-related macular degeneration (AMD) and central blindness.

Several recent observational studies have examined AMD prevalence, incidence, progression, or severity in relation to dietary patterns. Most of them used constructed scoring systems reflecting the level of adherence to specific dietary patterns by individuals. The European Eye (EUREYE) study examined associations between the prevalence of AMD and dietary patterns among 4,753 individuals from seven European countries. Adherence to the Mediterranean diet was assessed using a Mediterranean Diet Score system that captured high intakes of key food items, such as olive oil, wine, fruit, vegetables or salad, fish, and legumes, and low intakes of meat. High adherence to the Mediterranean Diet was associated with a reduced risk of developing large drusen, but there was no association with the risk of early or advanced AMD (63). In the Carotenoids in the Age-Related Eye Disease Study (CAREDS) that included 1,313 US women (ages, 50-79 years), high adherence to a Mediterranean-like dietary pattern characterized by high intakes of fruit, vegetables, whole grains, legumes, nuts, and fish, and moderate intakes of red meat and alcohol, were found to be associated with a 66% lower risk of early AMD (64). This Mediterranean-like dietary pattern, which is closer to dietary patterns occurring in the US, was also associated with a 26% lower risk of progression to advanced AMD in 2,525 subjects followed for a mean 8.7 years in the Age-Related Eye Disease Study (AREDS) (65). Of note, this association was no longer valid when the analysis was restricted to individuals with a genetically determined susceptibility to AMD, i.e., those homozygous for the risk allele of the *complement factor H [CFH]* gene (rs1410996) (65). A cross-sectional study that analyzed baseline data from 4,088 AREDS participants, among whom 2,739 had no AMD, 4,599 had early AMD, and 765 had advanced AMD, identified two main dietary patterns: so-called "Oriental" and "Western" patterns (66). High adherence to the "Oriental" dietary pattern characterized by consumption of vegetables, legumes, fruit, fish, whole grains, poultry, and low-fat dairy products was associated with lower risks of early and advanced AMD. In contrast, higher risks of early and advanced AMD were found in individuals with high adherence to a "Western" diet that included red and processed meat, potatoes, French fries, butter, high-fat dairy products, eggs, refined grains, and sweets and desserts (66).

Among observational studies that focused on individual food groups or nutrients, some have suggested that high intakes of fruit, vegetables, or antioxidant nutrients, such as vitamin C, vitamin E, and carotenoids, might be protective against AMD. In two early case-control studies, high intakes of dark-green leafy vegetables especially rich in lutein and zeaxanthin, two carotenoids present in the retina, were associated with a significantly lower risk of developing AMD (67, 68). In a prospective cohort study of more than 118,000 men and women, those who consumed ≥3 servings/day of fruit had a 36% lower risk of developing AMD over the next 12 to 18 years than those who consumed <1.5 servings/day (69). Interestingly, vegetable intake was not associated with the risk of AMD in this cohort. Another study combining lutein and zeaxanthin intake was not associated with the prevalence of intermediate AMD in a cohort of women aged 50-79 years (70). However, further analysis of the data revealed that women younger than 75 years with stable intakes of lutein and zeaxanthin had a 43% lower risk of developing intermediate AMD (70). In the AREDS trial, oral supplementation with β-carotene (15 mg/day), vitamin C (500 mg/day), vitamin E (400 IU/day), zinc (80 mg/day as zinc oxide), and copper (2 mg/day as cupric oxide) for five years was shown to reduce the risk of developing advanced AMD by 25% (71). In a follow-up study — the AREDS2 trial — supplemental lutein (10 mg/day) and zeaxanthin (2 mg/day) in combination with the 'AREDS formulation' only reduced the risk of progression to late AMD in the subset of participants with the lowest dietary intakes of lutein and zeaxanthin (72). A more detailed account of the epidemiological evidence regarding the relationship between dietary and supplemental carotenoids and AMD risk can be found in the article on Carotenoids.

Chronic obstructive pulmonary disease

Chronic obstructive pulmonary disease (COPD) is a condition that combines emphysema and chronic bronchitis, two chronic lung conditions that are characterized by airway obstruction. Smoking and indoor/outdoor pollution are considered to be primary contributors to COPD development, but dietary patterns low in fruit and vegetables and providing inadequate vitamin intakes may also affect lung function and risk for COPD (reviewed in 73, 74). Early observational studies in Europe indicated that higher fruit intakes, especially apple intakes, were associated with higher spirometric values (including forced expiratory volume in 1 second [FEV1]), indicative of better lung function (75-77). In a cross-sectional study of 2,500 middle-aged Welsh men, slower declines in lung function were associated with the consumption of at least five apples weekly compared to no consumption (76). Another study of 2,917 European men followed over 20 years found that each 100 g (3.5 oz) increase in daily fruit consumption was associated with a 24% lower risk of COPD-related mortality (78). Additionally, when compared to a Western dietary pattern of refined grains, cured and red meats, French fries, and desserts, a prudent diet emphasizing fruit, vegetables, fish, and whole grains was associated with a 25%-50% lower risk of COPD in two large cohorts of men (79) and women (80). In a large prospective cohort study that followed 44,335 Swedish men (mean age, 60.2 years) for a mean 13.2 years, the highest versus lowest quintile (≥5.3 servings/day versus <2 servings/day) of fruit and vegetable intakes was associated with a 35% lower risk of developing COPD (81). Subgroup analyses showed that fruit and vegetable intakes were inversely associated with COPD risk in current and former smokers, but not in men who never smoked. Because oxidative stress and inflammation play key roles in the etiology of chronic obstructive lung disease, it has been suggested that fruit and vegetables high in antioxidants, such as vitamin C, β-carotene, or flavonoids, could play a protective role against COPD. A three-year randomized controlled study in 120 patients with COPD (mean age, 68.1 years) assigned to a diet rich in antioxidants, such as fresh fruit, fruit juice, and vegetables, or a control diet has provided support for the antioxidant hypothesis (82). Shifting to a higher consumption of fruit and vegetables prevented the decline of lung function observed in subjects who consumed the control diet (82).

Asthma

Environment and lifestyle changes, including shifts toward unhealthy diets, are thought to contribute to the increasing prevalence of asthma and allergic diseases in industrialized countries. Observational studies that examined asthma and allergic symptoms in relation to fruit and vegetable intakes have provided mixed results (83). A cross-sectional analysis of a population-based study in 32,644 Portuguese adults identified five dietary patterns, of which one included fish, fruit, and vegetables — three essential components of the Mediterranean diet. This dietary pattern was found to be inversely associated with self-reported asthma symptoms and self-reported use of asthma drugs — yet not with self-reported medical diagnosis of asthma (84). In contrast, the most recent cross-sectional study of 3,202 participants in the European Global Allergy and Asthma Network of Excellence (GA^{2}LEN) showed no association between fruit and vegetable intake and risk of asthma and chronic rhino-sinusitis (85). A 2017 systematic review identified 58 studies (in addition to the two above-cited studies) reporting fruit and vegetable intake in relation to lung function, wheeze, or asthma, of which 30 were cross-sectional studies and 41 conducted in children and/or adolescents (83). A majority of studies (8 in adults and 22 in children) reported inverse associations between diets high in fruit and vegetables and risk of asthma and/or wheeze: 20 studies (8 in adults and 12 in children) showed that intakes of either fruit or vegetables were inversely associated with asthma and/or wheeze, and eight studies (one in adults and seven in children) found no associations. Pooled data analyses showed an inverse association between vegetable intake and risk of asthma, as well as fruit intake and asthma severity and risk of wheeze (83). A previous meta-analysis of observational studies reported lower risks of wheeze and asthma with higher intakes of fruit and vegetables in adults and children in cross-sectional studies, but not all prospective cohort studies have supported these findings (86). Subgroup analyses also suggested inverse associations between intakes of apples, citrus fruit, and tomatoes and risks of wheeze and asthma. Finally, pooled analyses of prospective cohort studies have revealed no association between fruit or vegetable intake during pregnancy and risk of wheeze or asthma in the offspring (86).

Cognitive decline and neurodegenerative disease

Observational studies

Results from most cross-sectional and longitudinal studies suggest that diets rich in fruit and vegetables might help prevent age-related cognitive deterioration and reduce the risk of neurodegenerative diseases like Alzheimer's disease (AD) (87). A 2014 systematic review identified 11 prospective cohort studies (88), of which four examined fruit and vegetable intakes in relation to incidence of neurodegenerative diseases. All four prospective studies reported inverse associations between consumption of fruit and vegetables and risk of developing mild cognitive impairments or dementia, including AD (89-92). Among the seven prospective cohort studies positively linking fruit and vegetable intakes to better cognitive performance (reviewed in 88), a two-year follow-up of 13,388 women (mean age, 74 years) in the Nurses' Health Study (NHS) found less cognitive decline in those in the highest versus lowest intakes of green leafy vegetables, cruciferous vegetables, and legumes (93). Fruit consumption was not associated with changes in cognitive performance in this study (93). However, a more recently published NHS study in 16,010 women analyzed intakes of major flavonoid-containing foods in relation to cognitive test scores and reported less cognitive decline with higher long-term intakes of strawberries and blueberries (94). Finally, a meta-analysis of 13 prospective cohort studies showed better global cognition in healthy older adults consuming the Mediterranean diet compared to control diets. In contrast, there were no differences in measures of episodic, semantic, and working memory between diets (95).

Dietary interventions

To date, only a few interventions have examined the overall effect of fruit- and vegetable-rich diets on cognition in cognitively healthy older adults. One trial assessed cognitive changes in 334 older adults (mean age, 66.9 years) at high risk for cardiovascular disease (CVD) randomly assigned to either a Mediterranean diet supplemented with extra-virgin olive oil, a Mediterranean diet supplemented with nuts, or a control diet (96). Following a median of 4.1 years, both Mediterranean diets prevented the deterioration of cognitive function that was observed in those ascribed the control diet. Compared to participants in the control diet group, those who followed the Mediterranean diet plus nuts had improved composite cognitive test scores for memory, while those in the Mediterranean diet plus olive oil group had better composite scores for frontal function and global cognition (96). However, in a six-month trial in 137 CVD-free Australian adults (mean age, 72 years), consumption of a Mediterranean diet rich in fruit, legumes, dairy, nuts, olive oil, and seafood did not result in improved cognitive function — measured by a battery of 13 neuropsychological tests — compared to the habitual diet (97, 98).

Mortality

Because regular consumption of fruit and vegetables may reduce the risk of some chronic diseases, it may also improve overall health and longevity. A 2017 meta-analysis of 95 prospective cohort studies found that daily consumption of fruit and vegetables was inversely associated with cause-specific and all-cause mortality (2). The risk of all-cause mortality was found to be 24% lower with five daily serving of fruit and vegetables combined (~400 mg/day) compared to little or no daily intake of fruit and vegetables. Five daily servings of fruit and vegetables were also associated with lower risks of cardiovascular-related (-19%) and cancer-related (-12%) mortality. In addition, the risk of all-cause mortality was lower with higher intakes of specific types of fruit and vegetables. There was evidence of lower risk of all-cause mortality with the highest versus lowest intake level of apples (-20%), berries (-8%), citrus fruit (-10%), cruciferous vegetables (-12%), and green leafy vegetables (-8%). This meta-analysis further reported a reduced risk of all-cause mortality with both cooked (-13%) and raw vegetable (-12%) intakes (2).

Although the Dietary Guidelines for Americans recommend fresh, frozen, and canned fruit equally, the consumption of the latter has been associated with increased risks of all-cause and cardiovascular related mortality in a pooled analysis of three UK-based prospective studies found with consumption of tinned fruit (99). While added sugar content in tinned fruit or exposure to bisphenol A (a chemical component of tin cans) may explain these results, further studies are needed to clarify whether fresh fruit and canned fruit can provide similar health benefits when included as part of a healthy diet.

Finally, although increasing daily intakes of fruit and vegetables would very likely reduce the number of premature deaths caused by cardiovascular disease and cancer in the US population, it is estimated that about 8 in 10 Americans do not meet the current intake recommendations (100).

Intake Recommendations

The 2015-2020 Dietary Guidelines for Americans — issued jointly by the US Department of Health and Human Services and the US Department of Agriculture — recommend to consume a healthy diet which includes, among other things, a variety of vegetables from all of the subgroups and fruit, especially whole fruit (101). In the 2015-2020 Dietary Guidelines for Americans, the unit of measure of a fruit or vegetable serving size is the cup-equivalent (c-eq). In general, one cup-equivalent of fruit corresponds to (1) one cup of cut-up, raw, or canned fruit; (2) one cup (eight fluid ounces) of 100% fruit juice; or (3) one-half cup of dried fruit. **Table 2** provides examples of the size of specific fruit counting as one cup-equivalent.

Table 2. What Counts as One Cup-equivalent of Fruit (adapted from 102)

Fruit	Examples of One Cup-equivalent of Fruit
Apple	1 small
Banana	1 large
Grapefruit	1 medium
Grapes	32 seedless grapes
Peach	1 large
Pear	1 medium
Plum	2 large or 3 medium
Strawberries	8 large berries
100% fruit juice	8 fluid ounces (1 cup)
Dried fruit (e.g., raisins, apricots)	½ cup

One cup-equivalent of vegetables generally corresponds to one cup of raw or cooked vegetables or vegetable juice. One exception is leafy greens (e.g., spinach, romaine, watercress, dark-green leafy lettuce, endive, escarole) for which one cup-equivalent corresponds to one cup of cooked or two cups of raw vegetables. **Table 3** provides specific examples of what counts as one cup-equivalent of vegetables.

Table 3. What Counts as One Cup-equivalent of Vegetables (adapted from 103)

Vegetables	Examples of One Cup-equivalent of Vegetables
Dark-green vegetables	
Greens (e.g., collards, kale)	1 cup, cooked
Raw leafy greens (e.g., watercress, endive, romaine)	2 cups, raw
Spinach	1 cup, cooked 2 cups, raw
Red and orange vegetables	
Carrots	1 cup, chopped, raw or cooked 2 medium 1 cup of baby carrots
Red peppers	1 large pepper
Tomatoes	1 large, raw 1 cup, chopped, raw, canned, or cooked
Sweet potatoes	1 large, baked
Legumes	
Dry beans and peas	1 cup, whole or mashed, cooked
Starchy vegetables	
Corn, yellow or white	1 large ear
White potatoes	1 medium, boiled or baked
Other vegetables	
Celery	1 cup, diced or sliced, raw or cooked 2 large stalks
Green peppers	1 large pepper
Lettuce	2 cups, raw, shredded or chopped
Onions	1 cup, chopped, raw or cooked

The 2015-2020 Dietary Guidelines for Americans provides dietary recommendations, including amounts of fruit and vegetables, designed to meet nutrient needs and Dietary Guidelines standards, for those who choose to follow either a healthy US-style eating pattern, a healthy Mediterranean-style eating pattern, or a healthy vegetarian eating pattern (101). The recommendations are based on estimated energy needs that vary with age, gender, and level of physical activity. Recommended daily intakes of fruit and vegetables at all calorie requirement levels can be found in the '2015-2020 Dietary Guidelines for Americans' report (see Appendices 3-5) (101). **Table 4** provides the amounts of fruit and vegetables (expressed in cup-equivalents) that are recommended at the 2,000-calorie per day level. Regardless of the chosen eating pattern, consumption of a variety of different vegetables and fruit is recommended, including all fresh, frozen, and canned dark-green, red, and orange vegetables, starchy vegetables, legumes (peas and beans), and all fresh, frozen, canned, and dried fruit and 100% fruit juice.

Table 4. 2015-2020 US Dietary Guideline Recommendations for Fruit and Vegetable Intakes*

Food	Healthy Eating Patterns		
	US-style	Mediterranean-style	Vegetarian
Vegetables (c-eq/day)	**2½**	**2½**	**2½**
Dark-green vegetables (c-eq/week)	1½	1½	1½
Red and orange vegetables (c-eq/week)	5½	5½	5½
Legumes (c-eq/week)	1½	1½	1½
Starchy vegetables (c-eq/week)	5	5	5
Other vegetables (c-eq/week)	4	4	4
Fruit (c-eq/day)	**2**	**2½**	**2**

*Recommendations for fruit and vegetable intakes at the 2,000-calorie per day level. Estimates of daily calorie needs according to age, gender, and physical activity can be found in the Appendix 2 of the '2015-2020 Dietary Guidelines for Americans' report (101).
c-eq, cup-equivalents

The nonprofit organization, Produce for Better Health Foundation (PBH), has partnered with the US Centers for Disease Control and Prevention (CDC) to develop the Fruits & Veggies — More Matters®health initiative, which aims to help Americans increase their consumption of fruit and vegetables for better health (104). Other initiatives like the US Department of Agriculture (USDA)'s ChooseMyPlate.gov have been developed to help everyone make healthier dietary choices, particularly by adding more fruit and vegetables to daily meals.

Finally, vegetables and fruit not only are a great source of micronutrients, dietary fiber, and unsaturated fat, they also supply a wide range of biologically active phytochemicals (**Figure 1**) that contribute to the health benefits of plant foods. Information regarding the functions and health benefits of specific micronutrients and phytochemicals can be found in articles on vitamins, minerals, and dietary phytochemicals.

Summary

- Cruciferous vegetables are unique in that they are rich sources of sulfur-containing compounds known as glucosinolates. *(More information)*
- Chopping or chewing raw cruciferous vegetables results in the formation of bioactive glucosinolate hydrolysis products, such as isothiocyanates and indole-3-carbinol. These metabolites are also generated by colonic bacteria, following the ingestion of cooked cruciferous vegetables. *(More information)*
- The biological activities of glucosinolate-derived isothiocyanates and indole-3-carbinol likely contribute to the potential health-promoting effects of cruciferous vegetables. *(More information)*
- Variations in the sequence of genes coding for Phase II detoxification enzymes, glutathione *S*-transferases (GSTs), may influence the potential health benefits of consuming cruciferous vegetables. *(More information)*
- A few observational studies have examined the link between cruciferous vegetable consumption and cardiovascular health, but the results have been largely inconsistent. *(More information)*
- High intakes of cruciferous vegetables have been associated with lower risk of bladder, breast, colorectal, endometrial, gastric, lung, ovarian, pancreatic, prostate, and renal cancer. However, evidence of associations remains largely limited to case-control studies. *(More information)*
- The Dietary Guidelines for Americans recommend for adults to consume 1½-2½ cup-equivalents of dark-green vegetables per week, including cruciferous vegetables, as part of healthy meals. *(More information)*

Introduction

Cruciferous or *Brassica* vegetables come from plants in the family known to botanists and biologists as Cruciferae or alternately, Brassicaceae. The Brassicaceae family, which includes the model plant *Arabidopsis thaliana*, comprises approximately 375 genera and over 3,000 species (1). Many, but not all, commonly consumed cruciferous vegetables come from the *Brassica* genus; examples include broccoli, Brussels sprouts, cabbage, cauliflower, collard greens, kale, kohlrabi, mustard, rutabaga, turnips, bok choy, and Chinese cabbage (2). Examples of other edible crucifers include radish (*Raphanus sativus*), horseradish (*Armoracia rusticana*), watercress (*Nasturtium officinale*), and wasabi (*Wasabia japonica*) (2).

Cruciferous vegetables are unique in that they are a rich source of sulfur-containing compounds called glucosinolates (β-thioglucoside N-hydroxysulfates) that impart a pungent aroma and spicy (some say bitter) taste (**Figure 1**). Glucosinolates can be classified into three categories based on the chemical structure of their amino acid precursors: aliphatic glucosinolates (e.g., glucoraphanin), indole glucosinolates (e.g., glucobrassicin), and aromatic glucosinolates (e.g., gluconasturtiin) (**Figure 1**) (1). Around 130 glucosinolate structures have been described to date (3), but only a subset can be found in the human diet. In a cohort of 2,121 German participants in the European Prospective Investigation into Cancer and Nutrition (EPIC study), glucobrassicin, sinigrin, glucoraphasatin (dehydroerucin), glucoraphanin, and glucoiberin were found to contribute most to total glucosinolate intake (4).

Glucosinolates and their breakdown derivatives (metabolites), especially isothiocyanates and indole-3-carbinol, exert a variety of biological activities that may be relevant to health promotion and disease prevention in humans (see the MIC articles on Indole-3-Carbinol and Isothiocyanates).

Plants synthesize glucosinolates from amino acids. Glucosinolates can be classified based on their amino acid precursors. Aliphatic glucosinolates are derived from alanine, leucine, isoleucine, valine, and methionine. Aromatic glucosinolates are derived from phenylalanine or tyrosine, and tryptophan is the precursor of indole glucosinolates (Ishida, 2014).

Metabolism and Bioavailability of Glucosinolates

Metabolism

The hydrolysis of glucosinolates, which is catalyzed by a class of enzymes called myrosinases (β-thioglucosidases), leads to the formation of breakdown compounds, such as thiocyanates, isothiocyanates, indoles, oxazolidine-2-thiones (e.g., goitrin), epithionitrile, and nitrile (**Figure 2**). In intact plant cells, myrosinase is physically separated from glucosinolates. Yet, when plant cells are damaged, myrosinase is released and comes in contact with glucosinolates, catalyzing their conversion into highly reactive metabolites. In plants, thiocyanates, isothiocyanates, epithionitrile, and nitrile are defensive compounds against pathogens, insects, and herbivores (1). When raw cruciferous vegetables are chopped during the cooking process, glucosinolates are rapidly hydrolyzed by myrosinase, generating metabolites that are then absorbed in the proximal intestine. In contrast, boiling cruciferous vegetables before consumption inactivates myrosinase, thus preventing the breakdown of glucosinolates. A small fraction of intact glucosinolates may be absorbed in the small intestine, but a large proportion reaches the colon (5). Of note, boiling cruciferous vegetables has also been found to reduce their glucosinolate content to a much greater extent than steam cooking, microwaving, and stir-frying do (5). Nonetheless, when cruciferous vegetables are cooked, bacterial myrosinase-like activity in the colon is mainly responsible for glucosinolate degradation, generating a wide range of metabolites (5, 6).

A neutral pH may favor the formation of isothiocyanates from glucosinolates (**Figure 2**). Once absorbed, isothiocyanates, such as glucoraphanin-derived sulforaphane, are conjugated to glutathione in the liver, and then sequentially metabolized in the mercapturic acid pathway (**Figure 3**). Sulforaphane metabolites — sulforaphane-glutathione, sulforaphane-glycine, sulforaphane-cysteine, and sulforaphane N-acetylcysteine (**Figure 3**) — collectively known as dithiocarbamates, are ultimately excreted in the urine (5).

Bioavailability

The composition and content of glucosinolates in cruciferous vegetables are relatively stable, yet depend on the genus and species and can vary with plant growing and post-harvest storage conditions and culinary processing (7, 8). Since most cruciferous vegetables are cooked prior to eating, bacterial myrosinase-like activity in the gut rather than plant myrosinase is responsible for the initial step in glucosinolate degradation (**Figure 2**). In a feeding study involving 45 healthy subjects, the mean conversion rate of glucosinolates (of which 85% was glucoraphanin) to dithiocarbamates over a 24-hour period was estimated to be around 12% with wide variations among participants (range, 1.1 to 40.7%) (7). In contrast, 70%-75% of ingested isothiocyanates were found to be metabolized to dithiocarbamates. Therefore, following the ingestion of cooked cruciferous vegetables, the conversion of glucosinolates into isothiocyanates by gut bacteria appears to be a limiting step in the generation of dithiocarbamates (7). However, differences in individuals' capacity to metabolize glucosinolates have not been linked to differences in gut microbiota composition (9).

Disease Prevention

Like most other vegetables, cruciferous vegetables are good sources of a variety of nutrients and phytochemicals that synergistically contribute to health promotion (see Bioactive compounds in cruciferous vegetables) (10). One challenge in studying the relationships between cruciferous vegetable intake and disease risk in humans is dissociating the benefits of whole diets that are generally rich in vegetables from those that are specifically rich in cruciferous vegetables (11). One characteristic that sets cruciferous vegetables apart from other vegetables is their high glucosinolate content (see Introduction). Glucosinolate hydrolysis products may play important roles in disease prevention by triggering antioxidant and anti-inflammatory response and contributing to the maintenance of cell homeostasis (see the MIC articles on Isothiocyanates and Indole-3-Carbinol).

Genetic influences

Once absorbed, glucosinolate-derived isothiocyanates (like sulforaphane) are promptly conjugated to glutathione by a class of phase II detoxification enzymes known as glutathione *S*-transferases (GSTs) (**Figure 3**). This mechanism is meant to increase the solubility of isothiocyanates, thereby promoting a rapid excretion in the urine. Isothiocyanates are thought to play a prominent role in the potential anticancer and cardiovascular benefits associated with cruciferous vegetable consumption (12, 13). Genetic variations in the sequence of genes coding for GSTs may affect the activity of these enzymes. Such variations have been identified in humans. Specifically, null variants of the *GSTM1* and *GSTT1* alleles contain large deletions, and individuals who inherit two copies of the *GSTM1*-null or *GSTT1*-null alleles cannot produce the corresponding GST enzymes (14). It has been proposed that a reduced GST activity in these individuals would slow the rate of excretion of isothiocyanates, thereby increasing tissue exposure to isothiocyanates after cruciferous vegetable consumption (15). However, human interventional studies with watercress report there is no difference in the isothiocyanate excretion rate between positive ($^{+/+}$) and null ($^{-/-}$) genotypes (16). Similar studies with broccoli have shown that *GSTM1*$^{-/-}$ individuals excreted a greater proportion of ingested sulforaphane via mercapturic acid metabolism than *GSTM1*$^{+/+}$ individuals (17, 18). In addition, GSTs are involved in "detoxifying" potentially harmful substances like carcinogens, suggesting that individuals with reduced GST activity might also be more susceptible to cancer (19-21). Finally, induction of the expression and activity of GSTs and other phase II detoxification/antioxidant enzymes by isothiocyanates is an important defense mechanism against oxidative stress and damage associated with the development of diseases like cancer and cardiovascular disease (22). The ability of sulforaphane (glucoraphanin-derived isothiocyanate) to reduce oxidative stress in different settings is linked to activation of the nuclear factor E2-related factor 2 (Nrf2)-dependent pathway. Yet, whether potential protection conferred by isothiocyanates via the Nrf2-dependent pathway is diminished in individuals carrying *GST*$^{-/-}$ variants is currently unknown.

Some, but not all, observational studies have found that GST genotypes could influence the associations between isothiocyanate intake from cruciferous vegetables and risk of disease (23).

Cardiovascular disease

High intakes of fruit and vegetables have been consistently associated with a reduced risk of cardiovascular disease (CVD) (24, 25). Yet, few observational studies have specifically examined the potential benefits of cruciferous vegetable consumption. In the Shanghai Women's Health Study (mean follow-up, 10.2 years) and the Shanghai Men's Health Study (mean follow-up, 4.6 years), which included a total of 134,796 Chinese adults, participants in the highest versus lowest quintile of cruciferous vegetable intakes had a 22% reduced risk of all cause-mortality and a 31% reduced risk of CVD-related mortality (26). In contrast, a pooled analysis of two large US prospective cohort studies, the Nurses' Health Study (70,870 women) and the Health Professionals' Follow-Up Study (38,918 men), found no significant association between cruciferous vegetable intake and combined risk of myocardial infarction (MI) and ischemic stroke (27). A case-control study conducted in 2,042 subjects (ages, <75 years) who survived a first acute myocardial infarction (MI), and matched healthy controls with no CVD history found that the individuals in the highest versus lowest tertile of cruciferous vegetable intakes (6 times/week versus <1 time/week) had 27% lower odds of MI (28). However, further analyses showed that the association between cruciferous vegetable intake and MI events was significant in individuals with two functional *GSTT1* alleles but not in carriers of two alleles of the *GSTT1* null variant ($^{-/-}$) (28).

Analysis of data from two 12-week randomized controlled trials in 130 participants with mild or moderate CVD risk found that the consumption of 400 g/week of high-glucosinolate broccoli (containing 3 to 6 times more glucoraphanin and glucoiberin than standard broccoli) resulted in a significant reduction in low-density lipoprotein (LDL)-cholesterol concentration in plasma compared with standard broccoli (29). Whether the effect of glucosinolates on cholesterol metabolism might be beneficial in the prevention of CVD needs further investigation.

Cancer

A recent intervention study demonstrated that cruciferous vegetables could increase the detoxification of carcinogens and other xenobiotics in humans. In this 12-week randomized controlled trial in 391 healthy Chinese adults exposed to high levels of air pollution, daily consumption of a broccoli sprout-rich beverage (providing 600 μmol/day of glucoraphanin and 40 μmol/day of sulforaphane) significantly increased the urinary excretion of a known carcinogen, benzene, and a toxicant, acrolein, compared to placebo (20). The biological activities of glucosinolate derivatives, isothiocyanates and indole-3-carbinol, which include modulation of xenobiotic metabolism, but also antioxidant and anti-inflammatory properties, induction of cell cycle arrest and apoptosis, and inhibition of angiogenesis, likely contribute to the potential benefits of cruciferous vegetables in the prevention of cancer (see the MIC articles on Isothiocyanates and Indole-3-Carbinol) (23).

Evidence from observational studies

Numerous observational studies have examined the relationship between cruciferous vegetable intake and cancer risk. Results from recent published meta-analyses of observational studies are reported in **Table 1** (adapted from 23).

Table 1. Cruciferous Vegetables and Cancer Risk: Meta-analyses of Observational Studies

Type of Cancer	Type of Observational Studies	Relative Risk [RR] or Odds Ratio [OR] (95% Confidence Interval)	Relative Risk [RR] in Subgroup Analyses (e.g., by food group or study type)	References
Bladder cancer	5 prospective cohort and 5 case-control studies	RR: 0.80 (0.69-0.92)	RR: 0.78 (0.67-0.89) with case-control studies only RR: 0.86 (0.61-1.11) with cohort studies only	Liu et al. (2013) (30)

	3 prospective cohort and 7 case-control studies	RR: 0.73 (0.63-0.83)	RR: 0.69 (0.60-0.78) for case-control studies RR: 0.96 (0.71-1.21) for cohort studies	Liu et al. (2013) (46)

Most meta-analyses found inverse associations between cruciferous vegetable intake and risk of bladder, breast, colorectal, endometrial, gastric, lung, ovarian, pancreatic, prostate, and renal cancer. Subgroup analyses showed that inverse associations remained significant in pooled analyses of case-control studies but not in pooled analyses of prospective cohort studies (see **Table 1**). Retrospective case-control studies are susceptible to bias in the selection of participants (cases and controls) and prone to dietary recall bias compared to prospective cohort studies, which collect dietary information from participants before they are diagnosed with cancer (47). The method of cooking cruciferous vegetables, which strongly affects the bioavailability and potential anticancer benefits of isothiocyanates (see Metabolism and Bioavailability of Glucosinolates) may be a source of bias and explain variation in the results of the studies (heterogeneity among studies). The lack of information regarding cooking methods prevented data adjustment to reduce bias.

In the past decades, some observational studies have examined the effect of individuals' genetic variations on the relationship between cruciferous vegetable intake and the risk of different cancer types. For example, a pooled analysis of two prospective cohort studies and six case-control studies found an inverse association between cruciferous vegetable consumption and risk of colorectal neoplasm in carriers of the *GSTT1* null variant but not in individuals with the *GSTM1* null variant or those with both the *GSTT1*and *GSTM1* null variants ($^{-/-}$) (36). The results of a pooled analysis of five case-control studies also suggested a stronger association between cruciferous vegetable intake and lung cancer in carriers of both the *GSTT1*$^{-/-}$ and *GSTM1*$^{-/-}$ variants compared to carriers of wild-type alleles ($^{+/+}$); however, it was not reported whether results from these two groups of individuals were significantly different (39). There is also a significant body of evidence suggesting that *GSTM1*$^{+/+}$ individuals gain greater cancer protection from consumption total cruciferous vegetables or broccoli compared to *GSTM1*$^{-/-}$ variant carriers (25, 48, 49). Current evidence is scarce, and adequately powered, well-designed studies are required to assess and explain potential interactions between cruciferous vegetable intake and GST genotypes.

A few observational studies have looked at whether cruciferous vegetable intake could be associated with reduced risks of disease progression and mortality. The highest versus lowest intake of cruciferous vegetables (assessed before diagnosis) was associated with a better survival rate over 72 months after diagnosis in 547 women with lung cancer (50). A prospective study in 29,361 men who underwent a prostate-specific antigen (PSA) test found that intake of cruciferous vegetables was inversely associated with risk of metastatic prostate cancer — cancer that has spread beyond the prostate (i.e., late-stage prostate cancer) — during a mean follow-up of 4.2 years (51). Another prospective study in 1,560 men diagnosed with non-metastatic prostate cancer reported that higher post-diagnosis intake of cruciferous vegetables was associated with a 59% lower risk of prostate cancer progression during a two-year period after completion of the dietary assessment (52). In contrast, cruciferous vegetable consumption in a cohort of 11,390 women with stage I-III invasive breast cancer (from four US and Chinese prospective studies), assessed about two years after diagnosis, was not found to be associated with risk of cancer recurrence or total mortality (53).

Nutrient Interactions

Iodine and thyroid function

Very high intakes of cruciferous vegetables, such as cabbage and turnips, have been found to cause hypothyroidism (insufficient production of thyroid hormones) in animals (54). Two mechanisms can potentially explain this effect. The hydrolysis of progoitrin, found in cruciferous vegetables (see **Figure 1**), may yield a compound known as goitrin, which may interfere with thyroid hormone synthesis. The hydrolysis of another class of glucosinolates, known as indole glucosinolates, results in the release of thiocyanate ions (see **Figure 2**) that can compete with iodine for uptake by the thyroid gland (55). However, increased exposure to thiocyanate ions from cruciferous vegetable consumption or, more commonly, from cigarette smoking, does not appear to increase the risk of hypothyroidism unless accompanied by iodine deficiency. One study in humans found that the consumption of 150 g/day (5 oz/day) of cooked Brussels sprouts for four weeks had no adverse effects on thyroid function (56). Similarly, consumption of high amounts of cruciferous vegetables has been associated with increased thyroid cancer risk only in iodine-deficient areas (57).

Intake Recommendations

The 2015-2020 Dietary Guidelines for Americans recommend eating a variety of vegetables daily (2½ cup-equivalents/day for a 2,000 calorie diet) from all of the five vegetable subgroups (dark green, red and orange, legumes, starchy, and other; see 58). No separate recommendations have been established for cruciferous vegetables, yet the 2015-2020 Dietary Guidelines for Americans recommend that adults consume 1½-2½ cup-equivalents of dark-green vegetables (which include cruciferous vegetables) per week (58).

Bioactive compounds in cruciferous vegetables

Cruciferous vegetables are important sources of some vitamins and minerals, fiber, and various phytochemicals other than glucosinolates (**Table 2**). Many of these compounds likely contribute to the potential health-promoting benefits of cruciferous vegetables.

Table 2. Some Potentially Beneficial Compounds in Cruciferous (*Brassica*) Vegetables

Vitamins	Minerals	Phytochemicals
Folate	Potassium	Carotenoids
Vitamin C	Selenium	Chlorophyll
Vitamin K	Calcium	Fiber
		Flavonoids
		Indole-3-Carbinol
		Isothiocyanates
		Lignans
		Phytosterols
		Sulfur bioactives (other than glucosinolates) (59)

Garlic and Organosulfur Compounds

日本語

Summary

- Garlic (*Allium sativum* L.) is a particularly rich source of organosulfur compounds, which are currently under investigation for their potential to prevent and treat disease. *(More information)*
- The two main classes of organosulfur compounds found in whole garlic cloves are L-cysteine sulfoxides and γ-glutamyl-L-cysteine peptides. *(More information)*
- Crushing or chopping garlic releases an enzyme called alliinase that catalyzes the formation of allicin from S-allyl-L-cysteine sulfoxide (Allin). Allicin rapidly breaks down to form a variety of organosulfur compounds. *(More information)*
- *In vivo* studies indicate that allicin-derived organosulfur compounds may be poorly bioavailable, whereas water-soluble derivatives of γ-glutamyl-L-cysteine peptides have been detected in plasma, liver, and kidney following oral consumption. *(More information)*
- Several different types of garlic supplements are available commercially, and each type provides a different profile of organosulfur compounds depending on how it was processed. *(More information)*
- Numerous preclinical studies reported that organosulfur compounds from garlic could exert antioxidant, anti-inflammatory, antimicrobial, anticancer, and cardioprotective activities in various experimental settings. *(More information)*
- The results of randomized controlled trials suggested that garlic supplementation modestly improves serum lipid profiles in individuals with elevated serum cholesterol and reduces blood pressure in hypertensive subjects, at least in the short term. It is not known whether garlic supplementation can help prevent cardiovascular disease. *(More information)*
- Current evidence from observational studies does not support an association between high intakes of garlic and prevention of cancer, including gastric and colorectal cancer. It is not known whether garlic-derived organosulfur compounds may be effective in preventing or treating human cancers. *(More information)*

Introduction

Garlic (*Allium sativum* L.) has been used for culinary and medicinal purposes in many cultures for centuries (1). Garlic is a particularly rich source of organosulfur compounds, which are thought to be responsible for its flavor and aroma, as well as its potential health benefits (2). Consumer interest in the health benefits of garlic is strong enough to place it among the best-selling herbal supplements in the United States (3). Scientists are interested in the potential for organosulfur compounds derived from garlic to prevent and treat chronic diseases, such as cancer and cardiovascular disease (4).

Organosulfur compounds from garlic

Two classes of organosulfur compounds are found in whole garlic cloves: L-cysteine sulfoxides and γ-glutamyl-L-cysteine peptides.

L-Cysteine sulfoxides

S-allyl-L-cysteine sulfoxide (alliin) accounts for approximately 80% of cysteine sulfoxides in garlic (**Figure 1**) (5). When raw garlic cloves are crushed, chopped, or chewed, an enzyme known as alliinase is released. Alliinase catalyzes the formation of sulfenic acids from L-cysteine sulfoxides (**Figure 2**). Sulfenic acids spontaneously react with each other to form unstable compounds called thiosulfinates. In the case of alliin, the resulting sulfenic acids react with each other to form a thiosulfinate known as allicin (half-life in crushed garlic at 23°C is 2.5 days). The formation of thiosulfinates is very rapid and has been found to be complete within 10 to 60 seconds of crushing garlic. Allicin breaks down *in vitro* to form a variety of fat-soluble organosulfur compounds (**Figure 2**), including diallyl trisulfide (DATS), diallyl disulfide (DADS), and diallyl sulfide (DAS), or in the presence of oil or organic solvents, ajoene and vinyldithiins (6). *In vivo*, allicin can react with glutathione and L-cysteine to produce S-allylmercaptoglutathione (SAMG) and S-allylmercaptocysteine (SAMC), respectively (**Figure 2**) (4).

γ-Glutamyl-L-cysteine peptides

Crushing garlic does not change its γ-glutamyl-L-cysteine peptide content. γ-Glutamyl-L-cysteine peptides include an array of water-soluble dipeptides, including γ-glutamyl-S-allyl-L-cysteine, γ-glutamylmethylcysteine, and γ-glutamylpropylcysteine (see **Figure 1**). Water-soluble organosulfur compounds, such as S-allylcysteine and SAMC (**Figure 3**), are formed from γ-glutamyl-S-allyl-L-cysteine during long-term incubation of crushed garlic in aqueous solutions, as in the manufacture of aged garlic extracts (see Sources).

Non-sulfur garlic phytochemicals

Although little is known about their bioavailability and biological activities, non-sulfur garlic phytochemicals, including flavonoids, steroid saponins, organoselenium compounds, and allixin, likely work in synergy with organosulfur compounds (6).

Metabolism and Bioavailability

S-Allyl-L-cysteine sulfoxide (Alliin)

In studies conducted in rodents, orally administrated alliin was found to be absorbed intact and to reach plasma and liver without being converted to allicin. There are no thiosulfinates (like allicin) in intact garlic cloves, and none can be generated in the stomach because alliinase would be irreversibly inhibited under acidic conditions (6).

Allicin and derivatives

The absorption and metabolism of allicin and allicin-derived compounds (see **Figure 2**) are only partially understood (7). In humans, no allicin has been detected in the serum or urine up to 24 hours after the ingestion of 25 g of raw garlic containing a significant amount of allicin (8). Before ingestion in garlic preparations and after ingestion in the stomach, allicin likely breaks down to release a number of volatile compounds, including DAS and DADS. These organosulfur compounds are metabolized to allyl mercaptan, allyl methyl sulfide, and allyl methyl disulfide, which have been detected in human breath after garlic consumption (9-11). Although a number of biological activities have been attributed to various allicin-derived compounds, it is not yet clear which of these compounds or metabolites actually reaches target tissues (5). Allyl methyl sulfide — but not allyl mercaptan — has been detected in the urine within four hours of garlic ingestion, suggesting that this compound is absorbed into the circulation and rapidly excreted (11). Other allicin-derived compounds, including diallyl sulfides, ajoenes, and vinyldithiins, have not been detected in human blood, urine, or stool, even after the consumption of up to 25 g of fresh garlic or 60 mg of pure allicin (5). These findings suggest that, if they are absorbed, allicin and allicin-derived compounds are rapidly metabolized.

γ-Glutamyl-S-allyl-L-cysteine and derivatives

γ-Glutamyl-S-allyl-L-cysteine is thought to be absorbed intact and hydrolyzed to S-allyl-L-cysteine (SAC) and *trans*-S-1-propenyl-L-cysteine (see **Figure 3**), since metabolites of these compounds have been measured in human urine after garlic consumption (12, 13). The consumption of aged garlic extract, a commercial garlic preparation that contains SAC, has been found to increase plasma SAC concentrations in humans (14-16). SAC has been detected in plasma, liver, and kidney of SAC-fed animals (17). Water-soluble organosulfur compounds like SAC and its metabolite, N-acetyl-S-allyl-L-cysteine, may be used as reliable markers of compliance in clinical trials involving garlic intake (6, 18).

Biological Activities

Antioxidant activity

Glutathione

Low cellular concentrations of glutathione, a major intracellular antioxidant, and/or overproduction of reactive oxygen species (ROS) can lead to oxidative stress-induced damage to biological macromolecules and contribute to the development and progression of pathological conditions. In endothelial cells (that line the inner wall of blood vessels), garlic-derived allicin lowered ROS production and increased the concentration of glutathione (19). Oral administration of allicin to mice lowered ROS production and prevented ROS-induced cardiac hypertrophy by inhibiting pro-inflammatory pathways like mitogen-activated protein kinase (MAPK) and phosphoinositide 3-kinase (PI3K)/protein kinase B (Akt)/glycogen synthase kinase 3β (GSK3β) signaling pathways (20). It is thought that, upon crossing cell membranes, allicin interacts with glutathione and forms SAMG (see **Figure 2**), which could prolong the antioxidant activity of allicin (19).

Nrf2-dependent antioxidant pathway

Allicin was also found to upregulate the expression of glutamate-cysteine ligase (GCL), the rate-limiting enzyme in glutathione synthesis, and other Phase II detoxifying/antioxidant enzymes, likely via the activation of the nuclear factor E2-related factor 2 (Nrf2)-dependent pathway (19). Briefly, Nrf2 is a transcription factor that is bound to the protein Kelch-like ECH-associated protein 1 (Keap1) in the cytosol. Keap1 responds to oxidative stress signals by freeing Nrf2. Upon release, Nrf2 translocates to the nucleus and binds to the antioxidant response element (ARE) located in the promoter of genes coding for antioxidant/detoxifying enzymes and scavengers. Nrf2/ARE-dependent genes code for numerous mediators of the antioxidant response, including GCL, glutathione S-transferases (GSTs), thioredoxin, NAD(P)H quinone oxidoreductase 1 (NQO-1), and heme oxygenase 1 (HO-1) (21). Like allicin, oil-soluble organosulfides, DADS and DATS (see **Figure 2**), have been shown to stimulate Nrf2-dependent antioxidant pathway (4). For example, antioxidant and cytoprotective effects of DADS against acute ethanol-induced liver damage in mice were associated with the ability to trigger Nrf2-dependent HO-1 activation (22). DATS protected cardiac cells *in vitro* and in experimental diabetic rats from high glucose-induced oxidative stress and apoptosis by inducing PI3K/Akt-dependent Nrf2 antioxidant signaling (23).

Aged garlic extract have also been shown to increase expression of antioxidant enzymes via the Nrf2/ARE pathway (24). SAC, a major organosulfur compound in aged garlic extract, prevented renal damage caused by ROS in cisplatin-treated rats, by limiting cisplatin-induced reduction of glutathione level, Nrf2 expression, and activity of several antioxidant enzymes (catalase, glutathione reductase, glutathione peroxidase) (25). SAC also protected neurons from oxidative damage and apoptosis in wild-type mice but not in mice without a functional Nrf2 signaling pathway (26).

Nitric oxide (NO) signaling cascade

The generation of nitric oxide (NO) catalyzed by endothelial nitric oxide synthase (eNOS) plays a critical role in protecting the vascular endothelium from oxidative and inflammatory insults (27). ROS-induced NO inactivation can impair vascular endothelial function, contributing to various pathologies like atherosclerosis, hypertension, cardiovascular disease, and central nervous system disorders (27, 28). Interestingly, ingestion of 2 g of fresh garlic was found to increase NO plasma concentrations within two to four hours in healthy volunteers (29). DADS and DATS protected eNOS activity and NO bioavailability in cultured endothelial cells challenged with oxidized low-density lipoprotein (LDL) (30). In a model of traumatic brain injury in rats, allicin attenuated brain edema, neurological deficits, and apoptotic neuronal death, and exhibited antioxidant and anti-inflammatory effects, partly by increasing Akt-mediated eNOS activation (31). Aged garlic extract and SAC were also found to stimulate NO production in different experimental settings (32). In a model of erectile dysfunction in diabetic rats, SAC restored electrically-induced penile erection by stimulating eNOS activity and inhibiting the expression of NADPH oxidase (Nox) responsible for ROS overproduction (33).

Anti-inflammatory activity

Garlic-derived organosulfur compounds have been found to inhibit mediators of the inflammatory response, including cytokines, chemokines, adhesion molecules, and enzymes like cyclooxygenase (COX), lipoxygenase (LOX), and inducible nitric oxide synthase (iNOS) (34-36). Nuclear factor-kappa B (NF-κB) is a transcription factor that binds DNA and induces the transcription of the *COX-2* gene, other pro-inflammatory genes, as well as genes involved in cell proliferation, adhesion, survival, and differentiation. The anti-inflammatory effects of organosulfur compounds result from their ability to counteract the activation of pro-inflammatory pathways — like NF-κB-, MAPK-, and PI3K/Akt-dependent signaling pathways — by pro-inflammatory stimuli (4). DATS inhibited bacterial lipopolysaccharide (LPS)-induced macrophage activation by limiting LPS binding to toll-like receptor 4 (TLR4) and blocking the upregulation of TLR4 and TLR4-associated molecule MyoD88 expression (37). DATS also inhibited LPS-induced NF-κB-dependent expression of COX-2, iNOS, tumor necrosis factor-α (TNF-α), and interleukin-1β (IL-1β) (37). In a mouse model of inflammation, the decrease of LPS-induced paw edema by DATS was associated with reduced serum concentrations of the pro-inflammatory cytokines, TNF-α, IL-6, and monocyte chemotactic protein-1 (MCP-1) (36).

Protection of the cardiovascular system

Inhibition of cholesterol synthesis

Garlic and garlic-derived organosulfur compounds have been found to decrease the synthesis of cholesterol by hepatocytes (38). Several garlic-derived organosulfur compounds, including S-allylcysteine and ajoene, have been found to inhibit 3-hydroxy-3-methyl-glutaryl-coenzyme A reductase (HMG-CoA reductase), a critical enzyme in the cholesterol biosynthesis pathway (39, 40). Garlic-derived compounds may also inhibit other enzymes in this pathway, including sterol 4α-methyl oxidase (41).

Inhibition of platelet aggregation

An increase in the ability of platelets to aggregate has been linked to the narrowing of blood vessels and the occurrence of acute thrombotic events. A variety of garlic-derived organosulfur compounds have been found to inhibit platelet aggregation in the test tube (42-44). Aged garlic extract was found to inhibit chemically stimulated platelet aggregation by downregulating the fibrinogen binding activity of glycoprotein IIb/IIIa fibrinogen receptor found on platelets (45, 46) and/or by preventing intraplatelet calcium mobilization (42).

Inhibition of vascular smooth muscle cell (VSMC) proliferation

The proliferation and migration of normally quiescent VSMCs are central features of vascular diseases, including atherosclerosis and coronary restenosis (when treated arteries become blocked again) (47). Although the significance of these findings for human cardiovascular disease is not yet clear, limited cell culture research suggested that organosulfur compounds from garlic could inhibit the proliferation and migration of VSMCs (39, 48, 49).

Inhibition of vascular cell adhesion molecules

An elevation of oxidized low-density lipoprotein (LDL) concentration in plasma has been involved in the pathogenesis of atherosclerosis. Oxidized LDL may stimulate the recruitment of inflammatory white blood cells from the blood to the arterial wall by inducing the expression of vascular cell adhesion molecules. DADS and DATS inhibited the expression of adhesion molecules, E-selectin and vascular cell adhesion molecule-1 (VCAM-1), on endothelial cell surface by reversing oxidized LDL-induced inhibition of PI3K/Akt and cAMP responsive element binding protein (CREB) signaling pathways (50).

Hydrogen sulfide-mediated vasodilatory activity

The preservation of normal arterial function plays an important role in cardiovascular disease prevention. Hydrogen sulfide (H_2S), a gaseous signaling molecule produced by some cells within the body, acts as a vasodilator (relaxes blood vessels) and thus may have cardioprotective properties (51, 52). H_2S production may be involved in vascular smooth muscle cell relaxation through regulating the opening/closing of potassium channels and/or enhancing NO-dependent signaling pathway (reviewed in 53). A study found that garlic-derived compounds are converted to hydrogen sulfide by red blood cells *in vitro* (54). However, human consumption of a high dose of raw garlic does not increase breath hydrogen sulfide levels, suggesting that significant metabolism of garlic compounds to hydrogen sulfide does not occur *in vivo* (11).

Note that the potential benefits of garlic consumption/supplementation on cardiovascular health may also be attributed to antioxidant and anti-inflammatory activities described above.

Anticancer activity

Effects on carcinogen metabolism

Inhibition of metabolic activation of carcinogens: Some chemical carcinogens do not become active carcinogens until they have been metabolized by Phase I biotransformation enzymes, such as those belonging to the cytochrome P450 (CYP) family. Inhibition of specific CYP enzymes involved in carcinogen activation inhibits the development of cancer in some animal models (55). In particular, DAS and its metabolites have been found to inhibit CYP2E1 activity *in vitro* (56, 57) and when administered orally at high doses to animals (58, 59). Oral administration of garlic oil and DAS to humans has also resulted in evidence of decreased CYP2E1 activity (60-62).

Induction of Phase II detoxifying enzymes: Reactions catalyzed by phase II detoxifying enzymes generally promote the elimination of drugs, toxins, and carcinogens from the body. Consequently, increasing the activity of phase II enzymes, such as glutathione S-transferases (GSTs) and NQO-1, may help prevent cancer by enhancing the elimination of potential carcinogens (see the Nrf2-dependent antioxidant pathway) (63). In animal studies, oral administration of garlic preparations and organosulfur compounds was found to increase the expression and activity of phase II enzymes in a variety of tissues (64-66). For example, DADS protected rodent liver against carbon tetrachloride (CCl_4; an environmental pollutant)-induced lipid peroxidation and cell necrosis by blocking CYP2E1-mediated CCL_4 metabolic activation and by upregulating Nrf2 downstream genes for NQO-1, HO-1, GCL, GST, and superoxide dismutase (SOD1) (67, 68).

Induction of cell cycle arrest

In normal cells, the cell cycle is tightly regulated to ensure faithful DNA replication and chromosomal segregation prior to cell division. When defects occur during DNA replication or chromosomal segregation and in case of DNA damage, the cell cycle can be transiently arrested at check points to allow for repair. Apoptosis is triggered when repair fails. Defective check points and evasion of apoptosis allow the unregulated division of cancer cells (69). Organosulfur compounds, including allicin, DAS, DADS, DATS, ajoene, and SAMC, have been found to induce cell cycle arrest when added to cancer cells in cell culture experiments (reviewed in 4, 70). DATS reduced the incidence of poorly differentiated prostate tumors and limited the number of metastatic lesions in the lungs of mice genetically modified to develop prostate adenocarcinomas (71). DATS was shown to inhibit cancer cell proliferation, as well as neuroendocrine differentiation — a hallmark of prostate cancer malignancy — but had no effect on apoptosis and markers of invasion (71). In a rat model of chemically induced colon cancer, inhibition of cell proliferation by aged garlic extract was associated with a reduction in the incidence of precancerous lesions and dysplastic adenomas, but not of adenocarcinomas (72).

Induction of apoptosis

Apoptosis is a physiological process of programmed death of cells that are genetically damaged or no longer necessary. Precancerous and cancerous cells are resistant to signals that induce apoptosis (73). Garlic-derived organosulfur compounds, including allicin, ajoene, DAS, DADS, DATS, and SAMC, have been found to induce apoptosis when added to various cancer cell lines grown in culture (reviewed in 4, 70). Oral administration of aqueous garlic extract and S-allylcysteine has been reported to enhance apoptosis in an animal model of oral cancer (74, 75). Garlic oil reduced the incidence of N-nitrosodiethylamine-induced liver nodules by preventing oxidative damage to lipids and DNA and by promoting apoptosis (76). Garlic oil upregulated the activity of various antioxidant enzymes and expression of pro-apoptotic effectors like Bax and Caspase-3 and downregulated the expression of the anti-apoptotic genes β-arrestin-2, Bcl-2, and Bcl-X (76).

Inhibition of angiogenesis

To fuel their rapid growth, invasive tumors must develop new blood vessels by a process known as angiogenesis. Anti-angiogenic properties of several organosulfur compounds, including alliin, DATS, and ajoene, have been observed in *in vitro* or *ex vivo* experiments (70). In human breast cancer cells, DADS inhibited TNF-α-induced release of MCP-1, a chemokine that promotes tissue remodeling, angiogenesis, and metastasis (77). Aged garlic extract was also found to suppress *in vitro* angiogenesis by inhibiting endothelial cell proliferation, loss of adhesion, motility, and tube formation (78).

Antimicrobial activity

Garlic extracts have been found to have antibacterial and antifungal properties (79, 80). Thiosulfinates, particularly allicin, are thought to play an important role in the antimicrobial activity of garlic (80-82). Allicin-derived compounds, including DATS and ajoene, also have some antimicrobial activity *in vitro* (5). To date, randomized controlled trials using oral garlic preparations have not provided strong evidence for such activity in humans (83-85). A small randomized controlled trial found that application of 1% ajoene cream to the skin twice daily was as effective in treating tinea pedis (fungal skin infection known as athlete's foot) as 1% terbinafine (Lamisil) cream (86). In another preliminary randomized controlled trial, circulating immune innate cells (γδT-lymphocytes and natural killer (NK) cells), isolated from healthy adults supplemented with aged garlic extract, proliferated better in *ex vivo* culture than those from volunteers who consumed a placebo, suggesting a greater pathogen-fighting ability. The number of self-reported illnesses was similar between groups after 90 days of aged garlic extract or placebo supplementation, but aged garlic extract significantly reduced the severity of self-reported cold or flu symptoms (87).

Disease Prevention

Cardiovascular disease

Interest in garlic and its potential to prevent cardiovascular disease began with observations that people living near the Mediterranean basin had lower mortality from cardiovascular disease (88). Garlic is a common ingredient in Mediterranean cuisine, but a number of characteristics of the "Mediterranean diet" have been proposed to explain its cardioprotective effects (89). Although few observational studies have examined associations between garlic consumption and cardiovascular disease risk, numerous intervention trials have explored the effects of garlic supplementation on cardiovascular disease risk factors.

Platelet aggregation

Platelet aggregation is one of the first steps in the formation of blood clots that can occlude coronary or cerebral arteries, leading to myocardial infarction or ischemic stroke, respectively. Evidence that garlic inhibits platelet aggregation is based mainly on *in vitro* experiments and a small number of *ex vivo* assays. Of 10 randomized controlled trials that tested the antithrombotic effect of garlic preparation, four reported a modest but significant decrease in *ex vivo* platelet aggregation with garlic supplementation compared to placebo (reviewed in 90). Because garlic oil extract in particular may have antithrombotic activity, a small randomized controlled trial in 12 healthy adults was conducted to test the acute effect of one large dose of garlic oil (extracted from 9.9 g of fresh garlic) on *ex vivo* platelet aggregation (91). The garlic oil extract had a mild effect on adrenaline-induced platelet aggregation (12% reduction) but had no effect on adenosine diphosphate (ADP)- or collagen-induced aggregation measured four hours post-consumption. Another study in 14 healthy volunteers showed that aged garlic extract dose-dependently inhibited ADP-stimulated platelet aggregation by downregulating the fibrinogen binding activity of glycoprotein IIb/IIIa fibrinogen receptor found on platelets (46).

Serum lipid profiles

A recent systematic review of randomized controlled trials examining the effect of supplementation with various garlic preparations on serum lipid profiles in individuals with elevated and normal serum cholesterol levels reported mixed results (92). The most recent and comprehensive meta-analysis compared the results from 39 randomized controlled trials published between 1955 and 2011 that tested the effect of garlic preparations on serum lipid concentrations (93). These 39 trials studied 2,298 adult participants (mean age, 49.5 years), administered garlic-only preparations, used a true placebo, and lasted for at least two weeks. The majority of included trials recruited subjects with elevated total cholesterol at baseline (>200 mg/dL [>5.2 mmol/L], 29 trials) and lasted more than eight weeks (30 trials). The authors found that garlic preparations significantly lowered total cholesterol and low-density lipoprotein (LDL)-cholesterol compared to placebo. High-density lipoprotein (HDL)-cholesterol concentrations were mildly increased and triglyceride concentrations were not affected by garlic supplementation. All administered garlic preparations (garlic powder, aged garlic extract, garlic oil, and fresh garlic) were well tolerated and associated with only minor side effects (garlic odor and mild gastrointestinal discomfort) (93).

Although garlic supplementation for a minimum of two months may lower total- and LDL-cholesterol concentrations in individuals with elevated total cholesterol, the benefits may not last beyond the short term (90, 92). Whether garlic possesses long-lasting lipid-lowering effects remain questionable and future investigations may focus on ways to maximize potential benefits of garlic preparations on serum lipids.

Atherosclerosis

Very few studies have attempted to assess the effect of garlic supplementation on the progression of atherosclerosis in humans. One early study in Germany used ultrasound imaging to assess the effect of 900 mg/day of dehydrated garlic on the progression of atherosclerotic plaque in the carotid and femoral arteries (94). After four years, the increase in plaque volume was significantly greater in women taking the placebo (+53.1%) than in women taking the garlic supplement (-4.6%), while no significant difference in plaque volume was found between garlic (+1.1%) and placebo (+5.5%) in men (94, 95). In a smaller pilot study, investigators measured coronary artery calcium using electron-beam computed tomography to assess the effect of supplementation with aged garlic extract on the progression of atherosclerosis in 19 adults already taking HMG-CoA reductase inhibitors (lipid-lowering drugs also known as statins) (18). After one year, increases in coronary artery calcium score were significantly lower in those taking aged garlic extract than in those taking a placebo. Nevertheless, although coronary calcium scores may have a predictive value regarding future cardiac events in asymptomatic subjects, it may not be a reliable marker of plaque burden in symptomatic patients (96, 97). In a recent double-blind, controlled study, the extent of coronary atherosclerosis was assessed with cardiac computed tomography angiography in 72 individuals (55 at study completion) at high risk of coronary heart disease randomized to receive either 2,400 mg of aged garlic extract or placebo for 52 weeks (98). The result suggested a significant decrease in the extent of coronary plaques with low-attenuation area (a type of vulnerable plaques prone to rupture) (99, 100) with aged garlic extract compared to placebo, but no differences in total plaque volume and proportions of non-calcified plaques and dense calcium were found between treatment and placebo groups (98).

Hypertension

Most systematic reviews and/or meta-analyses of randomized controlled trials to date have provided mixed results regarding the potential blood pressure-lowering effect of garlic, possibly because most of these trials enrolled both normotensive and hypertensive subjects (90, 101-105).

A systematic review and meta-analysis by Xiong et al. (106) included seven randomized, placebo-controlled trials that exclusively enrolled individuals with high blood pressure, i.e., with systolic blood pressure (SBP) ≥140 mm Hg and/or diastolic blood pressure (DBP) ≥90 mm Hg. Five out of seven trials identified in this systematic review reported statistically significant reductions in SBP and DBP with several garlic preparations (dried garlic homogenate, garlic powder, and aged garlic extract) (106). Another recent meta-analysis included nine randomized controlled trials in 482 hypertensive individuals who were given garlic powder (six studies), garlic homogenate (one study), aged garlic extract (two studies), or placebo for 8 to 26 weeks (107). Garlic preparations were found to significantly reduce SBP by a mean of 9.1 mm Hg and DBP by a mean of 3.8 mm Hg compared to placebo. The most recent meta-analysis found that garlic preparations reduced SBP by a mean 8.7 mm Hg (10 trials, 440 subjects) and DBP by 6.1 mm Hg (8 trials, 257 subjects) (102). Such reductions in blood pressure seem comparable to those reported with currently used classes of blood pressure-lowering medications (average reduction, -9.1 mm Hg for SBP and -5.5 mm Hg for DBP) (108). The effect of blood pressure reduction from such medications at standard dose has been estimated to lower the risk of coronary heart disease events by about one-quarter and the risk of stroke by about one-third (108). Nonetheless, evidence showing that garlic supplements may reduce the risk of cardiovascular morbidity and mortality is still lacking (109).

In a recent 12-week, randomized, placebo-controlled trial in untreated hypertensive subjects, daily intake of aged garlic extract (1.2 g of which contained 1.2 mg of S-allyl-L-cysteine [SAC]) was shown to significantly lower SBP by 11 mm Hg and DBP by 6 mm Hg on average in 50%-60% of participants, but reductions in blood pressure were not reported in 40%-50% of participants compared to placebo (110). Whether interindividual differences in nutritional status and genetic polymorphisms can explain differences in blood pressure response to garlic treatment need to be explored in future studies (53, 110).

Overall, short-term garlic supplementation appears to effectively reduce blood pressure with minimal side effects in hypertensive patients.

Summary

The results of randomized controlled trials have suggested that garlic supplementation modestly improves serum lipid profiles in individuals with elevated serum cholesterol and reduces blood pressure in hypertensive subjects. It is not yet clear whether garlic supplementation can reduce atherosclerosis or prevent cardiovascular events, such as myocardial infarction or stroke pressure in hypertensive subjects. It is not yet clear whether garlic supplementation can reduce atherosclerosis or prevent cardiovascular events, such as myocardial infarction or stroke.

Cancer

Gastric cancer

A recent meta-analysis of 17 studies (mostly case-control studies) reported an inverse association between high versus low garlic consumption and the risk of gastric cancer (111). Nevertheless, this conclusion is hindered by a number of limitations, especially related to the retrospective design of most studies included in the analysis, as well as great variations in the amount and duration of garlic intakes. In a 2009 review of the literature, Kim et al. (112) identified 20 human studies that examined garlic intake in relation to gastric cancer risk: three intervention studies, one case-cohort study, 13 case-control studies, and three cross-sectional/ecologic studies. Using the Food and Drug Administration (FDA)'s evidence-based criteria for the scientific evaluation of health claims (113), the authors excluded 16 studies for methodological flaws; only four studies (two case-control (114, 115), one case-cohort (116), and one intervention (85)) received moderate-to-high quality ratings (112). Among these four studies, garlic intake during adolescence or 20 years prior to the interview was not found to be associated with the risk of gastric cancer in one of the case-control studies in Sweden (338 gastric cancer patients and 669 control subjects) (114). Another case-control study in Korea failed to show an association between past garlic consumption and gastric cancer in 136 people diagnosed with gastric cancer and 136 cancer-free subjects (115). In addition, a prospective case-cohort study in the Netherlands found no association between the use of garlic supplements (unknown composition) and gastric cancer risk (116). Finally, a randomized, double-blind, placebo-controlled intervention study in 3,365 subjects from the Shandong province of China found that supplementation with aged garlic extract and steam-distilled garlic oil for 7.3 years did not reduce the prevalence of precancerous gastric lesions or the incidence of gastric cancer (85). An updated analysis of the data collected 7.3 years after garlic supplementation ended provided further confirmation for a lack of significant reduction in gastric cancer incidence or mortality with supplemental garlic (117).

***Helicobacter pylori* (*H. pylori*) infection and gastric cancer**: Infection with some strains of *H. pylori* bacteria markedly increases the risk of gastric cancer. Although garlic preparations and organosulfur compounds could inhibit the growth of *H. pylori* in the laboratory (118, 119), there is little evidence to suggest that high garlic intakes or garlic supplementation may help prevent or eradicate *H. pylori* infection in humans (120). Higher intakes of garlic were not associated with a significantly lower prevalence of *H. pylori* infection in China or Turkey (121, 122). Moreover, clinical trials using garlic cloves (123), aged garlic extract (84), steam-distilled garlic oil (84, 124), garlic oil macerate (125), or garlic powder (126) have not found garlic supplementation to be effective in eradicating *H. pylori* infection in humans.

Colorectal cancer

A 2014 meta-analysis of prospective cohort studies in 335,923 subjects (including 4,610 colorectal cancer [CRC] cases) found no association of consuming raw or cooked garlic (three studies, four cohorts) or supplemental garlic (four studies, five cohorts) with CRC (127). Another recent systematic review and meta-analysis that combined data from seven cohort and seven case-control studies also failed to find a statistically significant reduction in CRC risk with garlic intake (128). Yet, these results are in contrast with previous pooled analyses of data from case-control studies (129) or from both case-control and prospective studies (130) that reported an approximate 30% lower CRC risk in individuals with the highest garlic intakes compared to those with the lowest intakes. Inclusion of case-control studies, which are more susceptible to bias, may explain these discrepancies among meta-analyses (128). For information regarding different types of epidemiological studies, see the Spring/Summer 2016 LPI Research Newsletter.

A small preliminary intervention trial in 37 patients with colorectal adenomas examined whether supplementation with aged garlic extract for 12 months affected adenoma size and recurrence. Both the number and size of adenomas were significantly reduced in patients given a high dose of aged garlic extract compared to those given a much lower dose (0.16 mL/day) (131, 132). Larger randomized controlled trials are needed to determine whether garlic or garlic extracts can substantially reduce adenoma progression to advanced cancer and recurrence.

Other types of cancer

In a small, placebo-controlled intervention study in 50 patients with cancer (42 with liver cancer, seven with pancreatic cancer, and one with colon cancer), supplementation with 500 mg/day of aged garlic extract for six months failed to prevent quality of life deterioration caused by disease progression and chemotherapy-associated adverse effects (133). Yet, the active treatment limited the decline in natural killer cell count and activity that accompanies digestive cancer progression and reduces patient survival (133).

At present, evidence from trials is limited and results from observational studies do not suggest a role of high intakes of garlic in the prevention of cancer in humans (112).

Sources

Food sources

Allium vegetables, including garlic and onions, are the richest sources of organosulfur compounds in the human diet (134). To date, the majority of scientific research relating to the health effects of organosulfur compounds has focused on those derived from garlic. Fresh garlic cloves contain about 2 to 6 mg/g of γ-glutamyl-S-allyl-L-cysteine (0.2%-0.6% fresh weight) and 6 to 14 mg/g of alliin (0.6%-1.4% fresh weight). Garlic cloves yield about 2.5 to 4.5 mg of allicin per gram of fresh weight when crushed. One fresh garlic clove weighs 2 to 4 g (5).

Effects of cooking

The enzyme alliinase can be inactivated by heat. In one study, microwave cooking of unpeeled, uncrushed garlic totally destroyed alliinase enzyme activity (135). An *in vitro* study found that prolonged oven heating or boiling (i.e., six minutes or longer) suppressed the inhibitory effect of uncrushed and crushed garlic on platelet aggregation, but crushed garlic retained more anti-aggregatory activity compared to uncrushed garlic (136). Administering raw garlic to rats significantly decreased the amount of DNA damage caused by a chemical carcinogen, but heating uncrushed garlic cloves for 60 seconds in a microwave oven or 45 minutes in a convection oven prior to administration blocked the protective effect of garlic (137). The protective effect of garlic against DNA damage can be partially conserved by crushing garlic and allowing it to stand for 10 minutes prior to microwave heating for 60 seconds or by cutting the tops off garlic cloves and allowing them to stand for 10 minutes before heating in a convection oven. Because organosulfur compounds derived from alliinase-catalyzed reactions may play a role in some of the biological effects of garlic, some scientists recommend that crushed or chopped garlic be allowed to "stand" for at least 10 minutes prior to cooking (135).

Supplements

Several different types of garlic preparations are available commercially, and each type provides a different profile of organosulfur compounds depending on how it was processed (see **Table 1**). Not all garlic preparations are standardized, and even standardized brands may vary with respect to the amount and the bioavailability of the organosulfur compounds they provide (5).

Powdered (dehydrated) garlic

Powdered or dehydrated garlic is made from garlic cloves that are usually sliced and dried at a low temperature to prevent alliinase inactivation (138). The dried garlic is pulverized and often made into tablets. To meet United States Pharmacopeial Convention (USP) standards, powdered garlic supplements must contain no less than 0.1% γ-glutamyl-S-allyl-L-cysteine and no less than 0.3% alliin (dry weight) (139). Although powdered garlic supplements do not actually contain allicin, the manufacturer may provide a value for the "allicin potential" or "allicin yield" of a supplement on the label. These values represent the maximum achievable allicin yield of a supplement (140). It is determined by dissolving powdered garlic in water at room temperature and measuring the allicin content after 30 minutes (139). Because alliinase is inactivated by the acidic pH of the stomach, most powdered garlic tablets are enteric-coated to keep them from dissolving before they reach the neutral pH of the small intestine. It has been argued that it is more appropriate to measure "allicin release" using a USP method for assessing drug release from enteric-coated tablets under conditions that mimic those of the stomach and intestine (139). Allicin release by this method has been shown to parallel true bioavailability (140). Most tablet brands have been found to produce little allicin under these conditions, due mainly to low alliinase activity and prolonged disintegration times (140, 141). Many manufacturers provide information on the "allicin potential" of their powdered garlic supplements, but few provide information on the "allicin release." A number of controlled clinical trials have examined the effect of powdered or dehydrated garlic supplements on cardiovascular risk factors (see Cardiovascular disease). The most commonly used doses ranged from of 600 to 900 mg/day and provided 3.6 to 5.4 mg/day of potential allicin (90).

Garlic fluid extracts (aged garlic extract™)

When garlic cloves are incubated in a solution of ethanol and water for up to 20 months, allicin is mainly converted to allyl sulfides, which are lost by evaporation or converted to other compounds (138). The resulting extract contains primarily water-soluble organosulfur compounds, such as SAC and SAMC (see **Figure 3**) (142). Garlic fluid extracts, including aged garlic extracts, are standardized to their S-allyl-L-cysteine content. In controlled clinical trials, daily intakes of aged garlic extract at doses between 1.2 g-2.4 g (containing 1.2 to 2.4 mg of S-allyl-L-cysteine) consistently resulted in reductions in SBP by 9 mm Hg-10 mm Hg and reductions in DBP by 4 mm Hg-8 mm Hg in a majority of patients with uncontrolled hypertension (110, 143). Additionally, aged garlic extract at doses of 2.4 to 7.2 g/day resulted in short-term reductions in *ex vivo* platelet aggregation (144) and reductions in serum cholesterol concentrations up to 12 weeks (16).

Steam-distilled garlic oil

Steam distillation of crushed garlic cloves results in a product that contains mainly allyl sulfides, including DATS, DADS, and DAS (see **Figure 2**) (138). These fat-soluble steam distillation products are usually dissolved in vegetable oil.

Garlic oil macerates

Incubation of crushed garlic cloves in oil at room temperature results in the formation of vinyldithiins and ajoene from allicin, in addition to allyl sulfides, such as DADS and DATS (see **Figure 2**) (5). Ether extracts are similar in composition to garlic oil macerates but more concentrated (145).

Table 1. Principal Organosulfur Compounds in Commercial Garlic Preparations (4, 6)

Product	Principal Organosulfur Compounds	Delivers Allicin-derived Compounds?
Fresh garlic cloves	Cysteine sulfoxides (Alliin) γ-Glutamyl-L-cysteine peptides	Yes, when chopped, crushed, or chewed raw. Minimal, when garlic cloves are cooked before crushing or chopping.
Garlic powder (tablets)	Cysteine sulfoxides (Alliin) γ-Glutamyl-L-cysteine peptides	Varies greatly among commercial products. Enteric-coated tablets that pass the USP allicin release test are likely to provide the most.
Steam-distilled garlic oil (capsules)	Diallyl disulfide (DADS) Diallyl trisulfide (DATS) Allyl methyl trisulfide	Yes, but there is only 1% of oil-soluble sulfur compounds in 99% of vegetable oil.
Garlic oil macerate (capsules)	Vinyldithiins (E/Z)-ajoene Diallyl trisulfide	Yes
Aged garlic extract™ (tablets or capsules)	S-Allyl-L-cysteine (SAC) S-Allylmercaptocysteine (SAMC) *trans*-S-1-Propenyl-L-cysteine	Minimal

Safety

Adverse effects

The most commonly reported adverse effects of oral ingestion of garlic and garlic supplements are breath and body odor (90, 146). Gastrointestinal symptoms have also been reported, including heartburn, abdominal pain, belching, nausea, vomiting, flatulence, constipation, and diarrhea (106). The most serious adverse effects associated with oral garlic supplementation are related to uncontrolled bleeding. Several cases of serious postoperative or spontaneous bleeding associated with garlic supplementation have been reported in the medical literature (147-150). Garlic may also trigger allergic responses in some individuals, including asthma in people with occupational exposure to garlic powder or dust (151). Exposure of the skin to garlic has been reported to cause contact dermatitis in some individuals (146, 152). More serious skin lesions, including blisters and burns, have also been reported with topical exposure to garlic for six or more hours.

The safety characteristics of the various garlic preparations likely depend on their specific chemical composition (see **Table 1**). Aged garlic extract — the only water-based garlic supplement — showed a safe profile in toxicity studies and exhibited no undesirable side effects when combined with anticoagulants (warfarin), antiplatelets (aspirin), cholesterol-lowering (statins) drugs, or anticancer drugs (doxorubicin, 5-fluorouracil, methotrexate) in clinical settings (reviewed in 6). Safety and toxicity data are lacking for lipophilic (hydrophobic) garlic preparations, but some of their constituents have been shown to interfere with drug-metabolizing enzymes and transporters (see Drug interactions).

Pregnancy and lactation

No adverse effects on pregnancy outcomes have been reported when garlic is consumed in the diet. Although no adverse pregnancy outcomes were reported in a study of Iranian women who took dehydrated garlic tablets (800 mg/day) for two months during the third trimester of pregnancy (153), the safety of garlic supplements in pregnancy has not been established. There is some evidence that garlic consumption alters the odor and possibly the flavor of breast milk. In a controlled cross-over trial, oral consumption of 1.5 g of garlic extract by lactating women increased the perceived intensity of breast milk odor (154). Infants spent more time breast-feeding after their mothers consumed the garlic extract compared to a placebo, but the amount of milk consumed and number of feedings were not significantly different. Additionally, it is not known if topical use of garlic is safe during pregnancy or lactation.

Drug interactions

Anticoagulant medications

Garlic may enhance the anticoagulant effects of warfarin (Coumadin). There have been two case reports in which prothrombin time (INR) increased in patients who started taking garlic tablets or garlic oil without changing their warfarin dose or other habits (155). However, a more recent study in closely monitored patients on warfarin therapy found that garlic fluid extracts (aged garlic extract) did not increase hemorrhagic risk (156). Since garlic supplements have been found to inhibit platelet aggregation (90), there is a potential for additive effects when garlic supplements are taken together with other medications or supplements that inhibit platelet aggregation, such as high-dose fish oil or vitamin E (157). More research is needed to determine whether garlic supplements are safe for people on anticoagulatory therapy.

HIV protease inhibitors

Supplementation of healthy volunteers with garlic caplets twice daily (allicin yield, 7.2 mg/day) for three weeks resulted in a 50% decrease in the bioavailability of the protease inhibitor, saquinavir (Fortovase) (158). Although saquinavir undergoes significant metabolism by CYP3A4, supplementation with garlic extract for two weeks did not significantly alter a measure of CYP3A4 activity in healthy volunteers (159). Garlic extract supplementation (10 mg/day) for four days did not significantly alter single-dose pharmacokinetics of the protease inhibitor, ritonavir (Norvir), but further research is needed to determine steady-state interactions between well-characterized garlic supplements and ritonavir (160). *In vitro* hepatic models suggested that flavonoids and sulfur-containing compounds in garlic supplements might interfere with the activity of efflux drug transporters of the ATP-binding cassette (ABC) family, including P-glycoprotein, multidrug resistance protein (MRP), and breast cancer-resistance protein (BCRP), which function as ATP-dependent efflux pumps that actively regulate the excretion of a number of drugs limiting their systemic bioavailability. They may also affect the activity of phase I biotransformation enzymes like cytochrome P450 (CYP) 3A4 (CYP3A4) (161, 162). Modifications of efflux transporter and CYP3A4 activities may explain how supplementation with garlic phytochemicals might hinder the therapeutic efficacy of medications like antiretroviral drugs (162).

Summary

- Foods from the legume family include beans, peas, lentils, peanuts, and soybeans. *(More information)*
- Legumes are excellent sources of protein, low-glycemic index carbohydrates, essential micronutrients, and fiber. *(More information)*
- Substituting legumes for foods that are high in saturated fats or refined carbohydrates is likely to lower the risk of cardiovascular disease and type 2 diabetes mellitus. *(More information)*
- Regular consumption of legumes, both pulses (legumes excluding green peas, green beans, peanuts, and soybeans) and soy food, may result in favorable effects on blood lipid profiles by lowering LDL-cholesterol. *(More information)*
- Several observational studies have found non-soy legume intake to be inversely associated with incidence of prostate cancer. *(More information)*
- Lifelong exposure to soy food may be needed to lower risk of breast cancer. *(More information)*
- Short-term clinical trials have reported pulse consumption increases satiety; however, high-quality trials are needed to determine whether regular consumption of pulses results in weight loss in the long term. *(More information)*
- The most recent Dietary Guidelines for Americans include legumes in both the protein and vegetable groups, recommending a weekly intake of 1½ to 3 cup-equivalents of legumes for those who consume 2,000 calories/day. This recommended amount depends on the specific dietary pattern followed, and additionally, soy products are recommended for those who follow a vegetarian diet. *(More information)*

Introduction

Legumes are plants of the Leguminosae family with seed pods that split into two halves. Edible seeds from plants of this family include beans, peas, lentils, soybeans, and peanuts. The most recent Dietary Guidelines for Americans do not include green peas or green (string) beans as legumes due to a dissimilar nutritional profile when compared to the other legume family members (1). Peanuts are nutritionally similar to tree nuts; therefore, information on their health effects is presented in a separate article on Nuts and not discussed below. Many studies have examined how the consumption of pulses is related to health; pulses are legumes harvested as dry grain and thus exclude green peas, green beans, as well as crops used for oil extraction (soybeans, peanuts) (2).

Although legumes are an important part of traditional diets around the world, they are often neglected in typical Western diets. Legumes are inexpensive, nutrient-dense sources of protein that can be substituted for dietary animal protein (3). While sources of animal protein are often rich in saturated fats, the small quantities of fats in legumes are mostly unsaturated fats. Legumes are also good sources of several essential minerals, rich in dietary fiber (both soluble fiber and resistant starch), and considered to be low-glycemic index foods (4, 5). Moreover, legumes contain numerous phytochemicals that may affect health. Soybeans have attracted the most scientific interest, mainly because they are a unique source of phytoestrogens known as isoflavones (6). Overall, legumes represent unique packages of nutrients and phytochemicals that may work synergistically to reduce risk of chronic disease, as other edible seeds do (7).

Note: Research on the health effects of diets rich in legumes, including peas and soy foods, is summarized below. For a discussion of the potential health benefits and risks of soy isoflavones, see the separate article on Soy Isoflavones.

Disease Prevention

Type 2 diabetes mellitus

Consumption of legumes, which are rich in dietary fiber, other nutrients, and bioactive compounds, might help improve insulin sensitivity and regulate blood glucose concentrations, thereby influencing risk of type 2 diabetes mellitus.

Beans, peas, and lentils

The glycemic index is a measure of the potential for carbohydrates in different foods to raise blood glucose concentrations. In general, consuming foods with high-glycemic index values causes blood glucose concentrations to rise more rapidly, which results in greater insulin secretion by the pancreas, than after consuming foods with low-glycemic index values. Chronically elevated blood glucose concentrations and excessive insulin secretion are thought to play important roles in the development of type 2 diabetes mellitus (8). Low-glycemic load diets have been associated with reduced risk of developing type 2 diabetes in some, but not all, prospective cohort studies (see the article on Glycemic Index and Glycemic Load). High-fiber diets have also been associated with a decreased risk of type 2 diabetes (see the article on Fiber).

Together, the high-fiber content and low-glycemic index nature of legumes may contribute to help lower risk of type 2 diabetes in those who incorporate them into their daily diets. However, a 2017 meta-analysis of 12 prospective cohort studies found that higher legume intakes were not associated with risk of developing type 2 diabetes compared to lower intakes (range, 0-190 g/day; ~0-2 servings/day) (9), although a more recent prospective study not included in this pooled analysis found an inverse association (10).

Results of clinical trials of legume or pulse consumption have been more promising. A meta-analysis of 41 randomized controlled trials (some in individuals with normoglycemia and some in individuals with type 1 or type 2 diabetes) found that pulse consumption, either alone or in combination with a low-glycemic index diet or a high-fiber diet, improved some measures of glucose control, including fasting blood glucose and insulin concentrations, as well as markers of long-term glycemic control (11). The effect was stronger in patients with diagnosed diabetes compared to individuals with normoglycemia (11). In a three-month trial in 114 people with type 2 diabetes, those randomized to a low-glycemic diet that emphasized 1 cup/day of legumes had significant improvements in their hemoglobin A_{1C} value — the main fraction of glycated hemoglobin that reflects glycemic control over the past four months — compared to those randomized to a high-wheat fiber diet (12).

Small studies in healthy individuals have found that consumption of legumes improved postprandial glucose response at the subsequent meal (called the 'subsequent meal effect' or 'second meal effect') (13-15), although this has not been extensively studied. In addition to improving glycemic and insulin control, consumption of legumes may increase satiety and decrease both food intake and body weight, indirectly improving glycemic control (see Obesity below).

Soy

Observational studies on the association of soy intake and type 2 diabetes mellitus have reported mixed results. A 2018 meta-analysis of eight observational studies (six prospective cohort and two cross sectional) found an inverse association between soy intake and risk of type 2 diabetes; however, there was a high degree of heterogeneity in the analysis (16). Moreover, when a subgroup analysis was done and only prospective cohort studies were examined, the association was no longer significant (16).

A meta-analysis of 19 randomized controlled trials, including 1,518 participants, found that soy consumption — as soy foods/whole soy, isolated soy protein, or soy isoflavone supplements — had no effect on fasting glucose or insulin concentrations (17). Yet, subgroup analyses reported the effect on hyperglycemia differed by type of soy intervention: adherence to a whole-soy diet lowered fasting glucose concentrations, while soy protein isolate or isoflavone supplementation had no effect on fasting glucose concentrations (17).

Cardiovascular disease

Several characteristics of legumes may contribute to protection against cardiovascular disease. They are rich in soluble fiber and phytosterols, which are known to have cholesterol-lowering effects, and their high folate content may help lower homocysteine concentrations. Additionally, legumes are good sources of magnesium and potassium, which may decrease cardiovascular disease risk by helping to lower blood pressure (18). The low-glycemic index values of beans mean that they are less likely to raise blood glucose and insulin concentrations (see Type 2 diabetes mellitus above), and this may also decrease cardiovascular disease risk. Further, the substitution of legumes for foods high in saturated fat or refined carbohydrates may offer some cardioprotection.

Beans, peas, and lentils

Some, but not all, observational studies have found regular legume intake to be associated with a lower risk of cardiovascular events, and overall, most clinical trials have found legume consumption decreases cardiometabolic risk factors, especially circulating LDL-cholesterol concentrations. In a meta-analysis of eight prospective cohort studies, legume intake as part of a Mediterranean diet was associated with a 9% lower risk of cardiovascular disease, although one of the included studies grouped legume consumption with nuts, which are known to be cardioprotective (see the article on Nuts) (19). In a systematic review and meta-analysis of five prospective cohort studies, consuming four 100-g servings of legumes (beans, peas, lentils, tofu) weekly was associated with a 14% lower risk of coronary heart disease (CHD) (20). This association was driven mainly by a prospective cohort study that followed participants for 19 years, finding those who ate dry beans, peas, or peanuts at least four times weekly had a 21% lower CHD risk compared to those who ate them less than once weekly (21). Most recently, in a meta-analysis that included both CHD incidence and CHD-related mortality together as outcomes (eight prospective cohort studies in total), the highest versus lowest legume intakes were associated with a 10% decreased risk (22). In contrast, legume intake has not been linked to risk of stroke in four separate meta-analyses (20, 22-24).

Serum lipid profiles: Some, but not all, clinical trials have found that regular legume consumption results in favorable changes in the lipid profile. A 2014 systematic review and meta-analysis of 26 randomized controlled trials reported that pulse intake (beans, lentils, peas; median intake of 130 g/day or ~1.3 servings/day) reduced LDL-cholesterol concentrations by 0.17 mmol/L (6.6 mg/dL) compared to an isocaloric diet without pulses; however, there was no effect of pulse intake on non-HDL cholesterol or apolipoprotein B concentrations (25). It is important to note that there was significant heterogeneity among included trials of this meta-analysis, and the baseline lipid status of participants varied among the trials: eight trials included hyperlipidemic subjects, three trials were done in participants with normal lipid profiles, and 15 trials had a combination of normal and high lipid levels (25). A previous meta-analysis of randomized controlled trials found that non-soy legume consumption decreased total and LDL-cholesterol concentrations by 11.76 mg/dL (10 studies) and 7.98 mg/dL (9 studies), respectively, when compared to a matched control (matched for total calories or macronutrients; baseline total cholesterol concentrations of participants ranged from 199 to 295 mg/dL among studies) (26). A trend for a reduction in serum triglycerides (-18.94 mg/dL, p=0.05) was observed in this meta-analysis, and no effect on HDL cholesterol was found (26).

Hypertension: Adherence to the Dietary Approaches to Stop Hypertension (DASH) eating plan, which includes dry beans and peas among many other components (27), has been shown to reduce blood pressure (28), but it is not known whether legumes contribute to this effect. A 2014 meta-analysis of eight isocaloric, controlled feeding trials (median of 10 weeks' duration) — including both normotensive and hypertensive participants (n=554; median age, 49 years) — found that pulse consumption (median of 162 g/day or ~1.6 daily servings) decreased systolic blood pressure by 2.25 mm Hg but had no effect on diastolic blood pressure (29). It is important to note that there was significant heterogeneity among trials included in the meta-analysis (29).

Soy

Serum lipid profiles: In 1999, the US Food and Drug Administration (FDA) approved the following health claim: "Diets low in saturated fat and cholesterol that include 25 grams of soy protein a day may reduce the risk of heart disease" (30). Most of the evidence to support this health claim was included in the Anderson et al. meta-analysis of 38 controlled clinical trials that was published in 1995. This meta-analysis found that an average intake of 47 g/day of soy protein decreased serum total cholesterol concentrations by an average of 9% and LDL-cholesterol concentrations by an average of 13% (31). Hypocholesterolemic effects were primarily noted in individuals with high baseline cholesterol concentrations (31). A meta-analysis of 33 studies published since 1995 confirmed the hypocholesterolemic effect of soy protein reported in the Anderson et al. publication (32). Another meta-analysis of 30 studies in individuals with normal or mildly elevated cholesterol levels concluded that about 25 g/day of soy protein significantly lowers LDL-cholesterol concentrations by about 6% (33). Yet, a 2006 science advisory from the Nutrition Committee of the American Heart Association concluded that earlier research indicating that soy protein consumption results in clinically important reductions in LDL-cholesterol compared to other proteins has not been confirmed (34). A 2011 meta-analysis of randomized controlled trials, mostly in participants with hypercholesterolemia, found consumption of soy protein decreased LDL-cholesterol by 5.5% in parallel-design studies (20 trials; median soy protein intake of 31.5 g/day for a mean of 9.2 weeks) and 4.2% in cross-over studies (23 trials; median soy protein intake of 26.0 g/day for a mean of 6.0 weeks) — such decreases may translate to 6%-10% decreases in risk for coronary heart disease (35).

Consumption of isolated soy isoflavones (as supplements or extracts), however, does not appear to have favorable effects on serum lipid profiles (35-42).

In addition to possibly lowering cholesterol, incorporating soy foods into the diet may benefit overall cardiovascular health due to their relatively high content of polyunsaturated fat, fiber, and phytosterols compared to animal products (43).

Cancer

Legumes

Colorectal cancer: Legumes, including soybeans, contain fermentable dietary fiber and certain micronutrients and phytochemicals that may have anticancer effects. Some legumes contain serine protease inhibitors of the "Bowman-Birk family" (called Bowman-Birk inhibitors) that may have potential chemopreventive effects in the large intestine (44). Moreover, simply replacing red and processed meats, which are linked to a higher risk of colorectal cancer (45), with legumes in the diet might lower risk.

To date, observational studies of legume intake and colorectal cancer have reported conflicting findings. A meta-analysis of 14 prospective cohort studies found that higher legume intake was linked to a 9% lower risk of colorectal cancer, although there was significant heterogeneity among studies (46). Subgroup analyses revealed an inverse association between soybeans and colorectal cancer (RR, 0.85; 95% CI, 0.73-0.99) but not with dry beans and colorectal cancer (RR, 1.00; 95% CI, 0.89-1.13) (46). An earlier meta-analysis of cohort and case-control studies found that higher versus lower legume intake was associated with a 17% lower risk of colorectal adenoma (47).

Beans, peas, and lentils

Although beans, peas, and lentils are rich in a number of compounds that could potentially reduce the risk of certain cancers, the results of observational studies are too inconsistent to draw any firm conclusions regarding bean intake and cancer risk in general (48, 49).

Prostate cancer: Several prospective cohort studies have found non-soy legume intake to be inversely related to incidence of prostate cancer. In a six-year prospective study of more than 14,000 Seventh Day Adventist men living in the United States, those with the highest intakes of legumes (beans, lentils, or split peas) had a 47% lower risk of prostate cancer (50). In a prospective study of more than 58,000 men in the Netherlands, those with the highest intakes (median intake, 62 g/day) of legumes (including pulses and dried seeds) had a risk of prostate cancer that was 29% lower than those with the lowest intakes (median intake, 11 g/day) (51). Moreover, a prospective study in a multiethnic cohort of 82,483 men examined the risk of prostate cancer in men who consumed legumes excluding soy products. In this study, men who consumed the highest amount of non-soy legumes had a 10% lower risk of total prostate cancer and a 28% lower risk of nonlocalized or high-grade prostate cancer compared to those who consumed the least amount of non-soy legumes (52). However, another study found no association between dry bean intake and prostate cancer (53). Most recently, in a prospective study in 3,313 French men, non-soy legume consumption was linked to a 44% reduced risk of prostate cancer (54). A meta-analysis of these five prospective cohort studies found legume consumption was associated with a 15% lower risk of prostate cancer development (95% CI, 0.72-0.99) (55). Moreover, a pooled analysis of 13 prospective cohort studies found a similar association: a 14% lower risk of prostate cancer in men who consumed ≥100 g/day of mature beans (all beans excluding green beans and soybeans) compared to those who had intakes lower than 15 g/day (56).

Soy

Prostate cancer: Incidence rates of prostate cancer are much higher in North America, Northern and Western Europe, Australia, and New Zealand compared to Asian countries, such as Japan and China, where soy is common in the diet (57). Soy food consumption has been associated with a reduced risk of prostate cancer in pooled analyses of observational studies (58-62). In the most recent meta-analysis, total soy intake (16 studies) and unfermented soy intake (11 studies) were associated with a 29% and 35% lower risk of prostate cancer, respectively; no association was found between fermented soy intake and prostate cancer (eight studies) (62). Subgroup analyses revealed that the protective association of total soy intake was much stronger in case-control (39% lower risk) versus prospective cohort and nested case-control studies (10% lower risk) — unfermented soy intake was only associated with prostate cancer risk in case-control studies (45% lower risk) (62). Results of case-control studies are more likely to be distorted by bias (i.e., the selection bias with the selection of cases and controls, as well as dietary recall bias) than results of prospective cohort studies.

For a review of studies on soy isoflavone intake and prostate cancer, see the separate article on Soy Isoflavones.

Breast cancer: More than 25 observational studies have assessed the relationship between soy food intake and the risk of breast cancer. A 2008 meta-analysis of prospective cohort studies and case-control studies reported differential effects based on the typical level of soy consumption (63). In Asian populations, where soy intake is high, the authors found an inverse association between soy food intake and breast cancer; however, no association was observed in studies completed in Western populations, where soy food intake is much lower (63). A 2016 meta-analysis of 10 prospective cohort studies — four conducted in Japan, three in the US, two in China, and one in France — found that higher intake of soy food was associated with an 8% lower incidence of breast cancer compared to lower intake (64).

Age at exposure to soy might affect subsequent risk of developing breast cancer. For instance, a few case-control studies have reported that higher soy intake during childhood or adolescence was associated with a lower risk of developing breast cancer later in life (65-68). Soy intake later in life may not have as strong as an effect on breast cancer compared to exposure during childhood and adolescence (63), and lifelong exposure to soy food may be needed to lower risk of breast cancer (69).

Isoflavones are likely responsible for any protection of soy against the development of breast cancer; studies of soy isoflavone intake and breast cancer are reviewed in the separate article on Soy Isoflavones.

Endometrial cancer: Since soy isoflavones have estrogenic activity, studies have investigated whether isoflavone intake from soy food or supplements might be related to development of endometrial cancer. There is only limited evidence of an inverse association, primarily from case-control studies (70); see the separate article on Soy Isoflavones.

Gastrointestinal cancers: Results of observational studies examining soy intake and gastrointestinal cancers, including gastric cancer and colorectal cancer, have been mixed. A 2016 meta-analysis that included 18 case-control and 16 prospective cohort studies found soy consumption was associated with a 7% lower risk of gastrointestinal cancer; however, soy intake was not significantly linked to gastrointestinal cancer when the data from only cohort studies were considered (OR, 0.97; 95% CI, 0.90-1.03) (71). A separate meta-analysis reported soybean intake was associated with a 15% lower risk of colorectal cancer (95% CI, 0.73-0.99), but only three prospective cohort studies were included in this analysis (46). High-quality studies that control for potential confounders are needed to determine whether soy food intake — or legume intake in general — is linked to a lower risk of gastric or colorectal cancer.

Obesity

Numerous clinical trials have shown that consuming low-glycemic index food delays the return of hunger, decreases subsequent food intake, and increases the sensation of fullness compared to consuming high-glycemic index food (72, 73). Some trials have specifically examined the effect of legume or pulse consumption on food intake amount, satiety, or body weight. A 2016 meta-analysis that included 21 randomized controlled trials, mostly in overweight or obese subjects, reported an overall weight loss of 0.34 kg (0.75 lb) with diets that contained pulses (median intake 132 g/day for a median of six weeks; one serving ~100 g/day) (74). This analysis found a greater weight loss in negative-energy balance trials (i.e., energy-restricted diets; weight loss averaging 1.74 kg or 3.8 lb) than in neutral energy-balance trials (i.e., weight-maintenance diets; weight loss averaging 0.29 kg or 0.64 lb), although both effects were statistically significant (74). Six trials included in this meta-analysis examined the effect of pulse consumption (161 g/day; trial average duration of 10 weeks) on other measures of obesity: no effect was seen on waist circumference, but a trend for reduced body fat percentage was found with pulse consumption (p=0.07) (74). A meta-analysis of 21 controlled clinical trials (duration ranging from 4 weeks to 2 years) found that soy consumption — as whole soy or soy protein — had no effect on body weight, and a subgroup analysis showed that soy consumption actually increased body weight in obese subjects (75). Additionally, this meta-analysis found no effect of soy intake on fat mass (10 trials) or waist circumference (16 trials) (75).

A meta-analysis of nine acute, feeding trials in mostly normal-weight subjects reported pulse consumption, administered as a single bolus, increased measures of satiety by 31% compared to an isocaloric control; however, no effect on food intake at the subsequent/second meal was seen (seven trials) (76). Increases in acute satiety, likely due to the high protein and fiber content and the low-glycemic load of legumes, could lead to reduced food intake and the weight loss observed in some studies. Although currently available studies are limited, the effect on satiety appears to be following consumption of pulses and not soy food (reviewed in 77). High-quality trials are needed to determine whether regular pulse or legume consumption results in weight loss in the long term.

Cognitive health

Some studies have linked adherence to either the Dietary Approaches to Stop Hypertension eating pattern (78, 79) or a Mediterranean-style diet (78, 80-82) with better overall cognitive function in healthy older adults. Legumes are one of many components included in these dietary patterns that might contribute to this purported association; studies reporting specifically on legume intake and cognitive endpoints are limited and have reported mixed results. In a prospective cohort study of 2,613 middle-age and older adults (ages 43-70 years) residing in the Netherlands, followed for five years, legume intake was not associated with changes in global cognitive function (memory, speed of information processing, and cognitive flexibility) (83). In contrast, a prospective, nested case-control study of the Chinese Longitudinal Health Longevity Study found that older adults (≥65 years) who included legumes in their diets nearly every day had a 22% lower risk of cognitive decline over a three-year period compared to those who had lower intakes — this study included 5,691 illiterate older adults who had no evidence of cognitive decline at baseline (84). Most recently, a small study in 214 older, Italian adults (≥65 years) with normal cognitive function used the method of principal component analysis and identified legumes as one of the food categories linked to better cognitive scores at the end of a one-year period (85). Large-scale prospective cohort studies are needed to examine whether legume intake is associated with improvements in cognitive health or risk of dementia in older adults.

Mortality

A 2017 meta-analysis of six prospective cohort studies found a weak, inverse association between legume intake and risk of all-cause mortality (RR: 0.96; 95% CI: 0.94, 1.00) (86). In a large, international prospective cohort study (N=135,335) not included in the 2017 meta-analysis, stronger inverse associations were found with respect to all-cause mortality and non-cardiovascular mortality; however, legume consumption was not associated with cardiovascular-related mortality (87). In this study, consuming more than one serving of legumes daily was associated with a 42% lower risk of non-cardiovascular mortality and a 41% lower risk of all-cause mortality compared to consuming fewer than one legume serving per month (87). In a smaller prospective study (N=7,212) in Spain, conducted among older individuals at high risk for cardiovascular disease, non-soy legume intake was associated with a lower risk of cancer-related mortality but a higher risk of cardiovascular-related mortality (88). It is important to note that average intakes of legumes in this study were low, with those in the highest tertile consuming a mean 28 g/day of legumes — less than one-third of a serving (88). Moreover, a meta-analysis of prospective cohort studies did not find soy intake to be associated with all-cause (six studies), cardiovascular-related (six studies), or cancer-related (eight studies) mortality (89).

Intake Recommendations

Substituting beans, peas, and lentils for foods that are high in saturated fat or refined carbohydrates is likely to help lower the risk of type 2 diabetes mellitus and cardiovascular disease. Soybeans and foods made from soybeans (soy foods) are excellent sources of protein. In fact, soy protein is complete protein, meaning it provides all of the essential amino acids in adequate amounts for human health (6). Like beans, peas, and lentils, soy foods are also excellent substitutes for protein sources that are high in saturated fat like red meat or cheese. Legumes are not only good sources of protein and dietary fiber but also of vitamins, minerals, as well as phytochemicals that may benefit health (see **Table 1**).

The 2015-2020 Dietary Guidelines for Americans — healthy eating recommendations issued jointly by the US Department of Health and Human Services and the US Department of Agriculture — include legumes (beans, lentils, dried peas, and edamame [green soybeans]) in two different food groups: the protein group and the vegetable group (1). Recommended intake of legumes at the 2,000-calorie level translates to 1½ cup-equivalents weekly for those who follow a Healthy US-style or a Healthy Mediterranean-style eating pattern and 3 cup-equivalents weekly for those following a Healthy Vegetarian eating pattern (1). Current intakes of legumes among Americans are well below these recommendations (see Figure 2-4 in the Dietary Guidelines). The Dietary Guidelines also recommend 8 oz-equivalents/week of soy products for vegetarians consuming 2,000 calories/day and 5 oz-equivalents per week for those following other recommended eating patterns, although nuts and seeds can contribute to meet this recommendation. Moreover, fortified soy beverages are emphasized as alternative to dairy in the latest Dietary Guidelines (1).

Table 1. Some Potentially Beneficial Compounds in Legumes

Macronutrients	Vitamins	Minerals	Phytochemicals
Essential Fatty Acids	Folate	Iron	Fiber
	Niacin	Magnesium	Flavonoids
	Riboflavin	Potassium	Lignans
	Vitamin B_6	Zinc	Phytosterols
			Soy Isoflavones

Summary

- Nuts are good sources of several micronutrients, as well as unsaturated fatty acids, protein, fiber, and phytochemicals. *(More information)*
- Results from large prospective cohort studies show an association between regular nut consumption (≥5 ounces/week) and lower risk of coronary heart disease. There is strong evidence from randomized controlled trials that nut consumption lowers blood cholesterol concentrations. *(More information)*
- There is little evidence to support an association between regular nut consumption and a lower risk of developing type 2 diabetes mellitus. However, there is some evidence suggesting that nut consumption can improve glycemic control in individuals with type 2 diabetes mellitus. *(More information)*
- Current epidemiological data indicate that higher nut consumption does not result in greater weight gain; rather, incorporating nuts into the diet may benefit weight control and contribute to reductions in body weight and waist circumference in energy-restriction diets (i.e., weight-loss diets). *(More information)*
- Meta-analyses of prospective cohort studies show that nut consumption is associated with a reduced risk of all-cause mortality and mortality due to chronic conditions. *(More information)*
- Peanuts and tree nuts can cause life-threatening allergy reactions. Current guidelines for the primary prevention of allergy set by the National Institute of Allergy and Infectious Diseases discourage nut avoidance by non-allergic women during pregnancy and encourage the early introduction to peanuts in age-appropriate foods in infants with no peanut allergy. *(More information)*
- Substituting nuts for unhealthy snacks is a good strategy to avoid weight gain and improve the nutritional quality of one's diet. *(More information)*

Introduction

In the not too distant past, nuts were considered unhealthy because of their relatively high fat content. Recent research, however, suggests that regular nut consumption is an important part of a healthful diet. Although the fat content of nuts is relatively high (13-20 grams (g)/ounce), most of the fats in nuts are monounsaturated and polyunsaturated fats rather than saturated fats (see **Table 1**). The term "nuts" refers to tree nuts like almonds, Brazil nuts, cashews, hazelnuts, macadamia nuts, pecans, pistachios, and walnuts. Despite their name, peanuts are legumes like peas and beans. However, because they are nutritionally similar to tree nuts, they may share some of the same beneficial properties. Studies mentioned in this article have examined the effects of tree nuts and peanuts either together or separately.

Disease Prevention

Cardiovascular disease

In large prospective cohort studies, regular nut consumption has been consistently associated with significant reductions in the risk of coronary heart disease (CHD). An early study that followed more than 30,000 Seventh Day Adventists over 12 years found that participants who consumed nuts at least five times weekly had a 48% lower risk of death from CHD and a 51% lower risk of nonfatal myocardial infarction (MI) compared to those who consumed nuts less than once weekly (1). In addition, the risk of death from CHD was 39% lower in Seventh Day Adventists older than 83 years who ate nuts at least five times weekly compared to those who consumed nuts less than once weekly (2). More recently, an analysis of data from the Nurses' Health Study I that followed 84,136 women (ages at enrollment, 30-55 years) for 26 years reported a 32% lower risk of CHD in those who ate an average of 2.8 servings/week compared to those who never ate nuts (3). A 2014 meta-analysis of 13 prospective cohort studies, including the Seventh Day Adventists and Nurses' Health Studies, found a 34% lower risk of CHD with the highest versus lowest level of nut consumption (4). A dose-response analysis indicated that every 1 serving/week increment in nut consumption was associated with a 5% reduction in CHD risk (4). In another meta-analysis that included data from over 200,000 participants enrolled in three large cohort studies, weekly intake of at least five servings of nuts was associated with a 20% lower risk of CHD when compared to no consumption (5). However, there was no evidence of an association between nut consumption and risk of stroke. In contrast, another recent meta-analysis of prospective cohort studies found a 12% lower risk of stroke (14 studies) and a 19% lower risk of stroke-related death (seven studies) with the highest versus lowest intake of nuts (6).

The PREDIMED (Prevención con Dieta Mediterránea) study that took place between 2003-2011 was a multicenter, randomized controlled trial that examined the effect of a Mediterranean diet, with either extra-virgin olive oil or nuts, compared to a control diet, in the primary prevention of cardiovascular events in 7,447 adults (≥55 years) at high risk of cardiovascular disease (7). Adherence to a Mediterranean diet, supplemented with olive oil or mixed nuts for nearly five years resulted in a 30% lower risk of cardiovascular events and no weight gain (7).

Finally, a modeling study estimated that an increase in daily nut intake from 5 g to 30 g could have prevented 7,680 incidental cardiovascular events and saved about 65,000 years of life that were lost to stroke or heart attack in a scenario based on data from the Swedish population in 2013 (8).

Risk factors

Blood lipids: In a cross-sectional analysis of a representative sample of the US population — the National Health and Nutrition Examination Survey [NHANES] 2005-2010 — tree nut consumers (≥¼ ounce/day) were found to have higher blood HDL-cholesterol concentrations and lower body mass index (BMI), waist circumference, and systolic blood pressure than subjects consuming <¼ ounce/day (9). However, these observations may be due to reverse causation, in particular because health-conscious people are more likely to consume healthy diets that include nuts. A 2015 meta-analysis assessed the evidence of the effect of tree nut consumption on blood lipid profile using findings from 42 randomized controlled studies in a total of 2,101 participants, among which 45% were at risk of cardiovascular disease and untreated. Results indicated lower concentrations of total and LDL-cholesterol concentrations but no effect on concentrations of HDL-cholesterol or triglycerides (10). Similar observations were made in meta-analyses of interventions examining the specific effect of walnut (11, 12), almond (13), hazelnut (14), or pistachio (15) consumption on blood lipid profile of people with normal or elevated blood cholesterol. Interestingly, in a small recent trial in 46 statin-treated participants, the daily consumption of 100 g (~3.5 ounces) of almonds for four weeks led to a 4.9% reduction in non-HDL-cholesterol (i.e., total cholesterol minus HDL-cholesterol) concentration (16).

Blood pressure: Adherence to a Mediterranean diet for nearly four years in the PREDIMED trial led to significant improvements in diastolic (but not systolic) blood pressure compared to a control diet. However, there were no differences in blood pressure changes whether the Mediterranean diet was supplemented with nuts or olive oil (17). A meta-analysis of 21 randomized controlled trials in 1,652 participants found little evidence for an effect of nut supplementation on either systolic or diastolic blood pressure. A blood pressure-lowering effect of nuts was reported when only subjects without type 2 diabetes mellitus were considered. Of note, this meta-analysis included four trials that used either peanuts or soy nuts, which are not tree nuts (18).

Endothelial function: Measures of brachial flow-mediated dilation (FMD), a surrogate marker of endothelial function, are inversely associated with risk of cardiovascular events. A 2017 meta-analysis of eight randomized controlled trials suggested that supplementation with walnuts (four studies), pistachios (three studies), or almonds (one study) for up to 12 weeks may help increase FMD in subjects at risk of cardiovascular disease (19). Similar observations were reported in another recent meta-analysis of randomized controlled trials (20).

Chronic low inflammation: A 2016 meta-analysis of 20 small randomized controlled trials conducted primarily in subjects at high risk for cardiovascular disease found no evidence of an effect of nut supplementation for up to 12 weeks (only two studies lasted longer) on markers of inflammation in blood (21). Of note, four of the trials included in this meta-analysis exclusively supplemented participants with either peanuts or soy nuts. Nonetheless, a similar conclusion was reached in another meta-analysis of 25 interventions (19).

Of note, a recent systematic review of meta-analysis corroborated the account of the cardiovascular health benefits of nut consumption presented above (22).

Cardioprotective compounds in nuts

Nuts are energy-dense in particular because of their high fat content; yet, most of their fat is in the form of monounsaturated fatty acids (MUFAs) and polyunsaturated fatty acids (PUFAs). MUFAs and PUFAs are fatty acids that respectively contain one or more carbon-carbon double bonds (C=C) in their chemical structure, as opposed to saturated fatty acids that have none. Tree nuts contain more MUFAs than PUFAs with the exception of walnuts and pine nuts, which have more PUFAs than MUFAs, and Brazil nuts, which contain equivalent amounts of MUFAs and PUFAs (**Table 1**). Walnuts are especially rich in α-linolenic acid (~0.8 g/ounce), an omega-3 fatty acid with cardioprotective properties (see the article on Essential Fatty Acids). Other bioactive compounds, including micronutrients, phytosterols, and fiber, may also contribute to improving the cardiometabolic profile (**Table 1** and **Figure 1**). Some nuts (pecans, pistachios, almonds, and hazelnuts) are a source of flavonoids that may contribute to cardiovascular health (see the article on Flavonoids) (23). For more information on the nutrient content of nuts, search USDA's FoodData Central.

Table 1. Energy, Protein, Fat, Phytosterols, and Fiber in a 1-ounce Serving of Selected Tree Nuts and Peanuts

Nut (1 ounce[a])	Energy (kcal)	Protein (g)	Total fat (g)	MUFA[b] (g)	PUFA[c] (g)	Phytosterols (mg)	Fiber (g)
Almonds	164	6.0	14.2	8.9	3.5	39	**3.5**
Brazil nuts	187	4.1	19.0	6.8	6.9	21	2.1
Cashews	163	5.2	13.1	7.7	2.2	45	0.9
Hazelnuts	178	4.2	17.2	12.9	2.2	31	2.7
Macadamia nuts	**204**	2.2	**21.5**	**16.7**	0.4	33	2.4
Peanuts[d]	161	**7.3**	14.0	6.9	4.4	—	2.4
Peanut butter, smooth[d] (2 tbsp)	191	7.1	16.4	8.3	4.0	—	1.6
Pecans	196	2.6	20.4	11.6	6.1	36	2.7
Pine nuts (pignoli)	191	3.9	19.4	5.3	9.7	43	1.0
Pistachios	159	5.7	12.8	6.6	4.1	**61**	3.0
Walnuts, Black	175	6.8	16.8	4.4	**10.3**	34	1.9

The greatest contributions to energy, protein, fatty acids, phytosterols, and fiber are highlighted in bold.
[a]One serving of nuts ~1 ounce-equivalent (oz-eq) ~28 grams
[b]Monounsaturated fatty acids
[c]Polyunsaturated fatty acids
[d]Peanuts are legumes, related to beans, lentils, soybeans, and dried peas, yet they are nutritionally similar to tree nuts.

The US Food and Drug Administration (FDA) has acknowledged the current evidence for a relationship between nut consumption and cardiovascular disease by approving the following qualified health claim for nuts (24): "Scientific evidence suggests but does not prove that eating 1.5 ounces per day of most nuts (such as macadamia nuts (25)) as part of a diet low in saturated fat and cholesterol may reduce the risk of heart disease" (24).

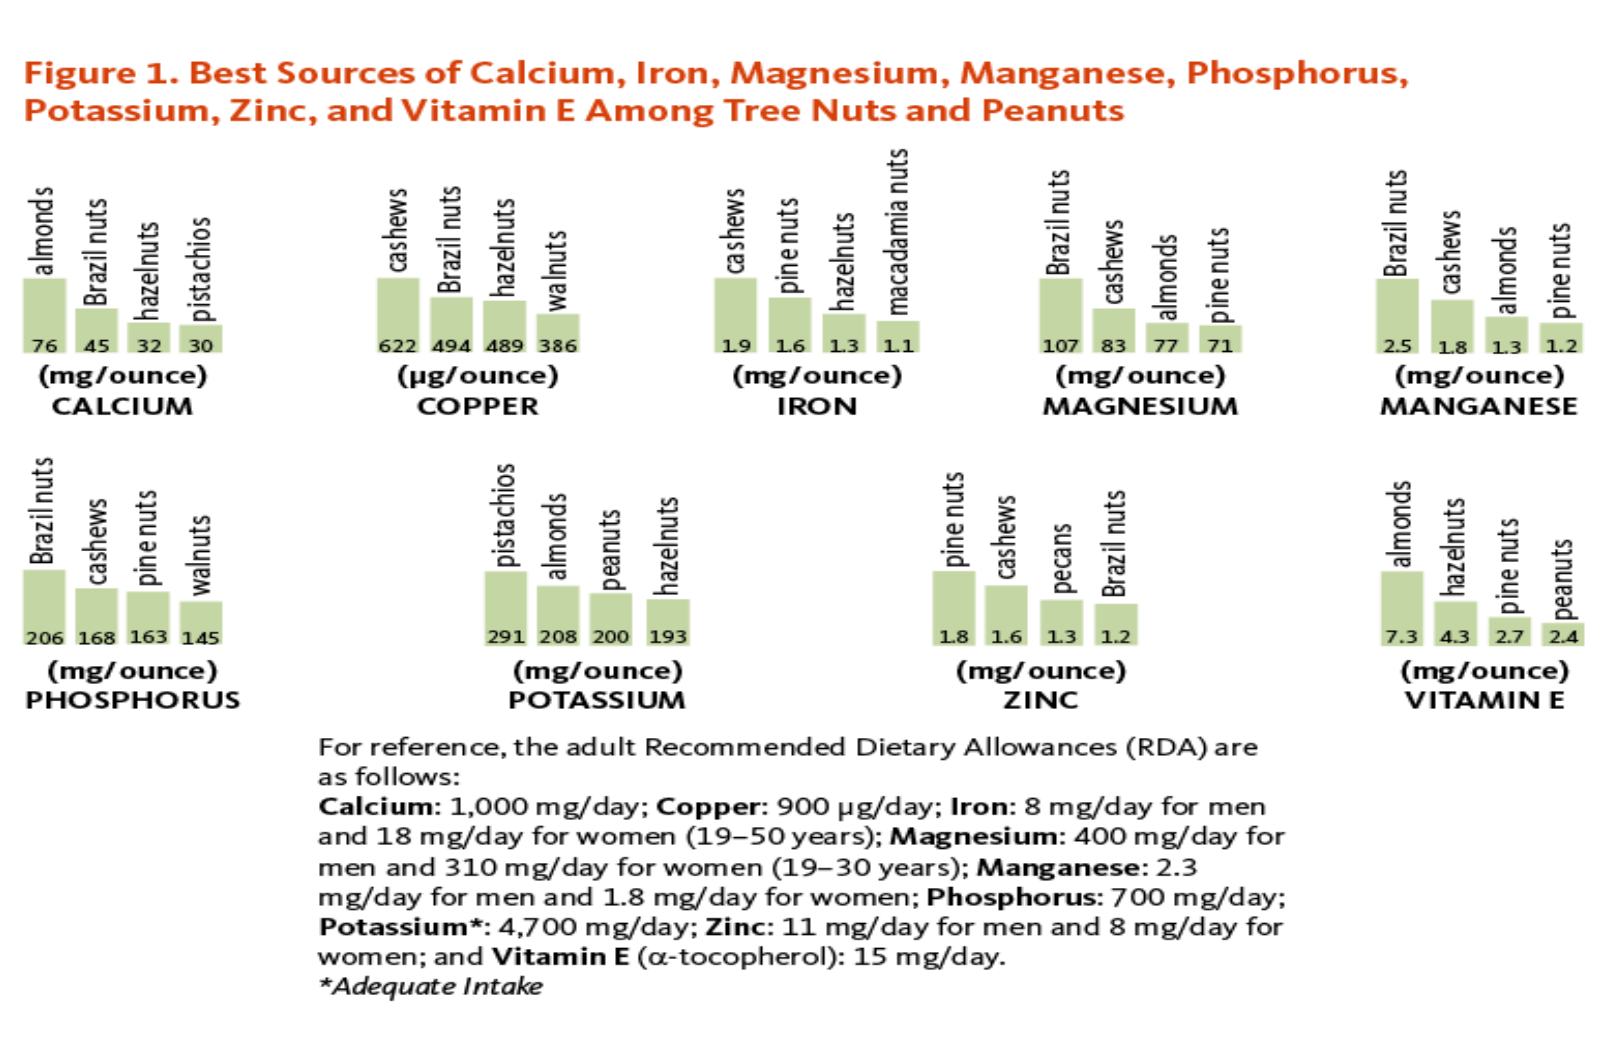

Figure 1. Best Sources of Calcium, Iron, Magnesium, Manganese, Phosphorus, Potassium, Zinc, and Vitamin E Among Tree Nuts and Peanuts

For reference, the adult Recommended Dietary Allowances (RDA) are as follows:
Calcium: 1,000 mg/day; **Copper**: 900 µg/day; **Iron**: 8 mg/day for men and 18 mg/day for women (19–50 years); **Magnesium**: 400 mg/day for men and 310 mg/day for women (19–30 years); **Manganese**: 2.3 mg/day for men and 1.8 mg/day for women; **Phosphorus**: 700 mg/day; **Potassium***: 4,700 mg/day; **Zinc**: 11 mg/day for men and 8 mg/day for women; and **Vitamin E** (α-tocopherol): 15 mg/day.
**Adequate Intake*

[Figure 1 - Click to Enlarge]

Type 2 diabetes mellitus

Early results from the Nurses' Health Study I suggested that nut and peanut butter consumption might be inversely associated with the risk of type 2 diabetes mellitus in women (26). However, two independent meta-analyses of more recent prospective cohort reported no evidence of an association between nut consumption and risk of type 2 diabetes (27, 28).

Nonetheless, a meta-analysis of 12 randomized controlled trials in 450 participants with type 2 diabetes showed that supplementation with tree nuts for a median of eight weeks could reduce fasting glucose concentration and glycated hemoglobin (HbA1c) concentration, a measure of glycemic control (29). Although there were no significant effects on fasting insulin concentration or a measure of insulin resistance (HOMA-IR) (29), these findings suggest that nuts might be part of a healthful diet for the management of hyperglycemia in individuals with type 2 diabetes.

Weight control

A frequent concern is that increased consumption of nuts, which are high in fatty acids and energy dense, may cause weight gain and obesity. A data analysis of NHANES 2005-2010 found that tree-nut consumers (≥¼ ounce/day) had significantly lower BMI and waist circumference than non-consumers (<¼ ounce/day) and were 23% less likely of becoming overweight or obese (9). In addition, in the European Prospective Investigation into Cancer and Nutrition study (EPIC-PANACEA) that followed 373,293 adults (ages, 25-70 years), weight gain over a five-year period was significantly lower (-0.07 kg) in those in the highest quartile of nut intake (median, 12.4 g/day) compared to non-consumers (30). Moreover, the risk of becoming overweight or obese was also 5% lower in those in the highest quartile of nut intake compared to non-consumers (30). A 2013 meta-analysis of small randomized controlled trials found that changes in measures of body weight (28 trials, 1,806 participants), BMI (14 trials, 1,057 participants), or waist circumference (5 trials, 681 participants) were similar when nut-rich diets were compared to standard diets (31). There was some weak evidence suggesting modest reductions in body weight, BMI, and waist circumference measures with nut-rich diets (compared to standard diets) in energy-restriction rather than weight-maintenance interventions (31).

Current epidemiological data indicate that higher nut consumption does not result in greater weight gain; rather, incorporating nuts into diets may be beneficial for weight control.

Finally, it has been suggested that higher amounts of protein and fiber in nuts could enhance satiety and suppress hunger (32). In a recent randomized controlled trial in 100 overweight or obese participants, weight loss and improvements in blood lipid profile and blood pressure over a six-month period were found to be similar regardless of whether walnuts were supplemented to a reduced-energy density diet (33). In addition, there was no difference in reports of satiety between groups (33).

Cancer

Only a few observational studies have examined nut intake in relation to cancer risk. In the Netherlands Cohort Study that followed 120,852 adults (ages, 55-69 years) for about 20 years, there was no association between tree nut, peanut, peanut butter, and total nut consumption and the risk of pancreatic cancer (34). Another analysis of data from 62,573 women in this cohort showed that the highest versus lowest quartile of total nut intake (≥10 g/day versus 0 g/day) was associated with a 45% reduced risk of certain breast cancer subtypes, namely ER- and ER-/PR- (estrogen receptor-negative/progesterone receptor-negative) breast cancers (35). Nut intakes were not associated with other breast cancer subtypes or total breast cancer (35). In a recent analysis of the NIH-AARP Diet and Health Study that followed 566,407 men and women (ages, 50-71 years) for a median 15.5 years, the highest versus lowest quartile (median, 2.20 g/1,000 kcal versus 0 g/1,000 kcal) of total nut intakes (walnuts, peanuts, seeds, and other nuts) was associated with a 27% lower risk of gastric noncardia adenocarcinoma (36). There were no associations between total nut intake and risk of gastric cardia adenocarcinoma, esophageal adenocarcinoma, or esophageal squamous cell carcinoma (36). Although nuts contain many anti-carcinogenic compounds, including some vitamins, minerals, unsaturated fatty acids, phytosterols, and fiber, there is very little evidence that nut consumption might protect against cancer.

Cognitive function

An analysis of NHANES data from the 1988-1994 and 1999-2002 surveys suggested higher scores on cognitive tests in participants (ages ≥20 years) with regular intakes of walnuts (>10 g/day) compared to non-consumers (37). In the Nurses' Health Study I, which included 19,415 women ≥70 years of age, the highest quintile of long-term nut intake (≥5 servings/week) was associated with higher scores on global cognition and verbal memory tests compared to the lowest quintile of intake (<1 serving/month) (38). However, total nut intake in this study was not linked to rate of cognitive decline among individuals over a six year-period (38). Results from the PREDIMED study in 522 participants (mean age, 74.6 years) at high vascular risk showed higher global cognition test scores in those assigned to a Mediterranean diet supplemented with either extra-virgin olive oil or mixed nuts compared to those fed a control diet for 6.5 years (39). Although participants in each intervention group were unlikely to be cognitively different as a result of randomization at the start of the study, baseline cognitive status was not assessed and thus the conclusions of this study are limited (39). A follow-up PREDIMED study in 334 older adults (mean age, 66.8 years) whose cognitive functions have been assessed both at enrollment and at study completion showed little-to-no evidence of differences in changes in individual test scores over four years between intervention groups and the control group (40). However, when composite test scores were considered to better describe cognitive functions, the result showed that the consumption of a diet supplemented with either extra-virgin olive oil or mixed nuts prevented the decline of global cognitive function, as well as verbal and episodic memory and frontal cognitive functions (attention, cognitive flexibility, and working memory), which was reported in the subjects randomized to the control diet.

Mortality

A meta-analysis of 15 prospective cohort studies, including 819,448 participants, found a 19% lower mortality risk with the highest versus lowest levels of total nut intake (41). Intakes of tree nuts (four studies), peanuts (five studies), and peanut butter (two studies), separately, were also inversely associated with mortality. In addition, there was a non-linear dose-response relationship between total nut intake and mortality, suggesting a greater benefit of increasing intakes when intakes are initially low and no additional protection with intakes beyond 15 to 20 g/day. Higher intakes of total nuts were also found to be inversely associated with mortality related to respiratory disease (three studies) and diabetes mellitus (four studies) (41). These results corroborated findings from other recent meta-analyses (27, 42, 43).

It has been hypothesized that nut consumption could reduce the risk of disease and prolong life through influencing the length of telomeres that protect the ends of chromosomes. Bioactive compounds in nuts might regulate oxidative stress and inflammation, which are important drivers of telomere shortening, a marker of biological aging. A few cross-sectional studies have examined the associations between nut consumption and leukocyte telomere length, yet the findings have been rather inconsistent (44-47).

Safety

Nut allergies

Peanuts and tree nuts are among the most common foods to trigger allergic reactions, potentially severe (anaphylaxis) and fatal (48). Such reactions can be triggered by a primary antibody response against some nut proteins or by antibodies raised against protein in pollen but cross-reacting with structurally similar proteins in nuts. Mixed method-based estimates of peanut allergy in US children suggest that the condition is increasingly prevalent and ranges between 2 and 5% (49). Estimates based solely on self reports suggest a prevalence of tree nut allergy <1% in US adults and <2% in US children (50). Individuals with peanut or tree nut allergies need to take special precautions to avoid inadvertently consuming peanuts or tree nuts by checking labels and avoiding unlabeled snacks, candies, and desserts (50). See the Food Allergy Research and Education website for additional tips to avoiding unintentional peanut or tree nut exposure.

Nut consumption during pregnancy and lactation

In the 2010 'Guidelines for the Diagnosis and Management of Food Allergy in the United States,' the National Institute of Allergy and Infectious Diseases discourages nut avoidance during pregnancy or breastfeeding as a way of preventing food intolerance in the offspring (51). Results from two birth cohort studies suggested an inverse association between maternal peanut or tree nut consumption during, shortly before, or just after their pregnancy and the risk of food allergy (including nut allergy) in the offspring (52, 53), supporting the current recommendations. Yet, prior studies found higher peanut consumption in mothers of children with peanut allergy (54). Additional studies are needed to clarify the effect of maternal nut intake on food tolerance in the offspring.

Introduction to peanuts during infancy

A 2017 addendum to the 2010 'Guidelines for the Diagnosis and Management of Food Allergy in the United States' included recommendations for the prevention of peanut allergy through the early introduction of peanuts in infants' diet (55) (**Table 2**).

Table 2. 2017 Recommendations for the Introduction of Age-appropriate Peanut-containing Foods for Peanut Allergy Prevention (55)

Infant Criteria	Earliest Age for Peanut Introduction	Recommendations
Severe eczema and/or egg allergy	4-6 months	• Peanut introduction only after measurement of peanut-specific antibodies and/or skin prick testing are found negative. • Peanut introduction should start after the introduction of solid foods without peanuts. • Infant may still benefit from early peanut introduction even if the 4-6 month window is missed.
Mild-to-moderate eczema	~6 months	• Introduce peanut-containing foods.
No eczema or food allergies	Age-appropriate and in accordance with family preferences	• Introduce peanut-containing foods.

Adverse effects

Brazil nuts grown in areas of Brazil with selenium-rich soil may provide more than 100 μg of selenium in one nut, while those grown in selenium-poor soil may provide 10 times less (56). For information regarding toxicity of selenium, see the article on Selenium.

Intake Recommendations

Regular nut consumption, equivalent to 1 ounce of nuts five times weekly, has been consistently associated with significant reductions in risk of coronary heart disease in epidemiological studies. Consuming nuts daily as part of a diet that is low in saturated fat has been found to lower serum total and LDL-cholesterol in a number of controlled clinical trials. Since an ounce of most nuts provides at least 160 calories (kcal), simply adding an ounce of nuts daily to one's habitual diet without eliminating other foods may result in weight gain. Substituting unsalted nuts for less healthy snacks or for meat in main dishes are two ways to make nuts part of a healthful diet. A modeling study that used 2009-2012 NHANES data from 17,444 individuals (≥1 year old) estimated that substituting tree nuts for between-meal snacks on a calorie-per-calorie basis would improve the nutritional quality of dietary intakes through a shift in fatty acid intake (less saturated and more unsaturated fatty acids), a reduction in added sugar and sodium (salt), and an increase in potassium, magnesium, and fiber (57).

The 2015-2020 Dietary Guidelines for Americans encourage the consumption of nuts, seeds, and soy products as part of a healthy diet. The recommendations are presented in **Table 3**.

Table 3. 2015-2020 Dietary Guidelines for Americans: Recommendations[a] for Nuts, Seeds, and Soy Products

Life Stage	Age	Mediterranean-style or US-style Eating Patterns[c]	Vegetarian Eating Pattern[d]
Children	2-3 years	2-3	2-3
Children	4-8 years	2-4	2-7
Children	9-13 years	4-5	5-9
Adolescents	14-18 years	4-6	6-13
Adults	19 years and older	5-6	7-10

[a]Dietary guidelines apply when no quantitative Dietary Reference Intake (DRI) value is available.
[b]The recommendations in ounce-equivalent (oz-eq) per week are based on estimated energy needs that vary with age and gender (see Appendix 2: Estimated Calorie Needs per Day, by Age, Sex, and Physical Activity Level). Recommended weekly intakes of nuts, seeds, and soy products, at all calorie requirement levels can be found in the '2015-2020 Dietary Guidelines for Americans' report.
[c]Recommended amounts for nuts, seeds, and soy products.
[d]Recommended amounts for nuts and seeds. Separate recommendations are made for soy products.

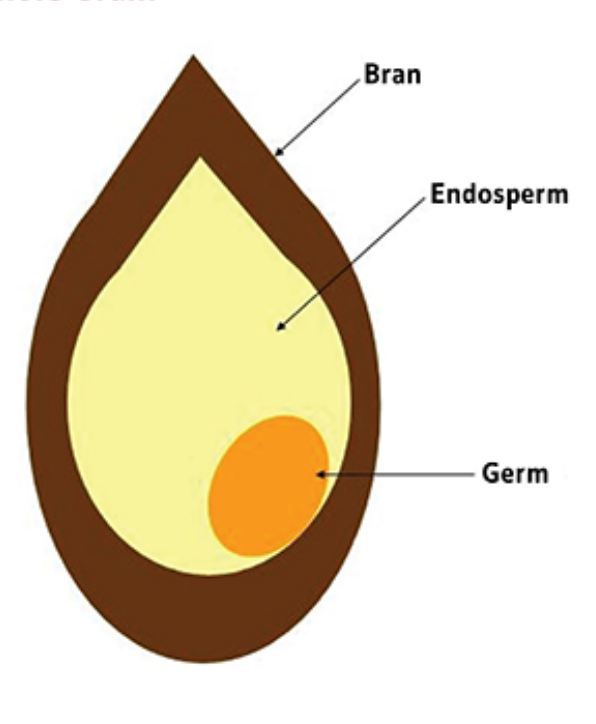
- References

- endosperm, and the germ, are retained in the same relative proportions as in the intact grain. (More information)
- Bran and germ, which are lost during the refining (milling) process, are rich in minerals, vitamins, phytochemicals, and dietary fiber that play important roles in the health benefits associated with whole-grain consumption. *(More information)*
- There is no consensus as to what constitutes a whole-grain food. Products that bear the FDA health claims for whole grains contain at least 51% of whole-grain ingredients by weight. *(More information)*
- Observational studies have found that diets rich in whole grains are associated with reduced risks of type 2 diabetes mellitus and cardiovascular disease compared to diets high in refined grains. *(More information)*
- Although the protective effects of whole grains against cancer are not as well established as those against cardiovascular disease and type 2 diabetes mellitus, some prospective cohort studies have found whole-grain intake to be associated with a decreased risk of esophageal and colorectal cancers. *(More information)*
- Results from large prospective cohort studies showed that whole-grain consumption was inversely correlated with all-cause mortality and mortality from several conditions, including cardiovascular disease, cancer, type 2 diabetes mellitus, respiratory disease, and infections. *(More information)*
- Diets rich in whole grains and fiber may help prevent constipation in healthy people and the formation of pouches (diverticula) in the wall of the colon. In a recent prospective cohort study, higher intakes of dietary fiber, especially from cereal and fruit, was associated with a significantly lower risk of diverticular disease. *(More information)*
- The 2015-2020 Dietary Guidelines for Americans recommend consuming a minimum of three servings (about 90 g) of whole-grain products daily. *(More information)*

Introduction

Grains are seeds of plants belonging to the Poaceae family (also called Gramineae or true grasses). Some examples of edible grains include wheat, rice, maize (corn), barley, oats, rye, triticale (wheat-rye hybrid), millet, bulgur, and sorghum (1). Although they are not members of the Poaceae family, whole-grain ingredients also include pseudo-grains like quinoa, amaranth, and buckwheat. A whole grain has an outer layer of bran, a carbohydrate-rich middle layer called the endosperm, and an inner germ layer (**Figure 1**). Whole-grain foods contain entire grain seeds either intact, cracked, crushed, or flaked, as long as the bran, endosperm, and germ are retained in the same proportions as they exist in the intact kernel (1). Whole grains are rich in potentially beneficial compounds, including vitamins, minerals, fiber, and phytochemicals, such as lignans and phytosterols (2). Most of these compounds are located in the bran or the germ of the grain, both of which are lost during the refining (milling) process, leaving only the starchy endosperm (1). Compared to diets high in refined grains, diets rich in whole grains are associated with reduced risks of several chronic diseases. The health benefits of whole grains are not entirely explained by the individual contributions of the nutrients and phytochemicals they contain. Whole grains represent a unique package of energy, micronutrients, and phytochemicals that work synergistically to promote health and prevent disease (3).

Figure 1. Anatomy of a Whole Grain



Disease Prevention

Because there is no globally accepted definition as to what constitutes a whole-grain food, it is difficult to compare studies that examined the effects of whole-grain consumption on markers of health and disease outcomes. The US Food and Drug Administration (FDA) approved health claims for whole grains (see Finding whole grain foods) to foods containing ≥51% of whole-grain ingredients by weight or ≥8 g of whole grains per one ounce (~30 g)-serving size (4). An international multidisciplinary expert group recently proposed to label "whole grain" a food with a whole-grain content of ≥8 g per ounce (5). Yet, to date, most epidemiological studies that examined the health impact of consuming whole-grain foods have included foods containing ≥25% of whole grains and added brans by weight (6).

Type 2 diabetes mellitus

A recent meta-analysis of eight large prospective cohort studies, including 385,868 participants, have found that high versus low intakes of total grains and whole grains were associated with a significant reduction in the risk of developing type 2 diabetes mellitus (7). On the other hand, no relationship was found between refined-grain intake and diabetes in a meta-analysis of six prospective studies of 258,078 subjects (7). Specifically, the consumption of three daily servings of whole-grain foods was associated with a 32% lower risk of diabetes (see below for Examples of one serving of whole grains). Further analyses showed a significantly lower risk of diabetes with high versus low consumption of whole grains as a single food (i.e., brown rice, wheat bran) or as an ingredient in food (i.e., whole-grain bread, whole-grain breakfast cereal) but not with refined grains like white rice and wheat germ (7). In addition, a pooled analysis of three large prospective cohorts — the Health Professionals Follow-up Study [HPFS] and the Nurses' Health Studies [NHS I and II] — reported a 17% increased risk of type 2 diabetes in participants in the highest (≥5 servings/week) versus lowest (<1 serving/month) quintile of white rice intake, while brown rice consumption (≥2 servings/week versus <1 serving/month) was associated with an 11% reduction in risk (8). Interestingly, substituting 50 g/day (⅔ serving/day) of brown rice or other whole grains for the same amount of white rice could be associated with a predicted diabetes risk reduction of 16% or more (8).

Whole grains and glucose control

Whole grains have been hypothesized to reduce the risk of type 2 diabetes mellitus by improving postprandial glycemia. Immediately after a meal, blood glucose and lipid concentrations are increased, and secretion of insulin by the pancreas stimulates glucose and lipid storage into tissues. Prolonged postprandial hyperglycemia and hyperlipidemia have been associated with oxidative stress, inflammation, insulin resistance, and endothelial dysfunction, all contributing to the development of chronic diseases like type 2 diabetes mellitus (9). The refining process that removes bran and germ facilitates the digestion of the carbohydrate-rich endosperm such that carbohydrates from refined grains were thought to elicit a higher and more rapid elevation in blood glucose, as well as a greater demand for insulin, than whole grains (10). However, compared with foods made from refined grains, whole-grain products do not necessarily have a lower glucose-raising potential, i.e., a lower glycemic index (GI) (11). The GI concept is based on the idea that foods containing carbohydrates that are easily digested, absorbed, and metabolized have a high GI (GI ≥70 on the glucose scale); in contrast, foods containing slowly digestible carbohydrates that elicit a reduced postprandial glucose response are considered to have a low GI (GI ≤55 on the glucose scale) (see also the article on Glycemic Index and Glycemic Load) (12). Bread, breakfast cereal, rice, and snack products have been attributed either a low or high GI, whether or not they include whole grains (11), suggesting that the type of food rather than its whole-grain content affects postprandial blood glucose concentrations.

In some observational studies, higher whole-grain intakes have been associated with decreased insulin resistance (13) and increased insulin sensitivity (14) in healthy individuals. In a controlled cross-over trial in 11 overweight or obese adults, consumption of a diet rich in whole grains for six weeks lowered several clinical measures of insulin resistance compared with a diet high in refined grains (15). However, in a recent randomized controlled study of 61 adults with metabolic syndrome, the consumption of a diet based on several whole-grain cereal products for 12 weeks had no effect on fasting plasma concentrations of glucose, insulin, lipids, or on insulin resistance compared with a refined grain-based diet. Yet, postprandial plasma insulin and triglycerides — but not postprandial plasma glucose — were significantly reduced with the whole grain-based diet (16). A decreased postprandial insulin response may be associated with an increase in tissue sensitivity to insulin (3). In another intervention trial in 20 healthy volunteers, three-day consumption of whole barley-based bread induced a lower insulin peak value following a standard breakfast than the same course with refined wheat bread. Whole barley-based bread consumption was also associated with an increase in circulating concentrations of gut-related hormones (e.g., peptide YY, glucagon-like peptide) and a higher gut fermentation activity. This suggested improvements in hormonal control of digestion and in colonic fermentation of resistant starch (indigestible fiber) (17), possibly promoting the feeling of satiety (18) and increasing insulin sensitivity (19).

Whole-grain consumption might be improving insulin sensitivity rather than blunting postprandial hyperglycemia; however, well-designed, large randomized controlled trials are necessary to provide further insight into how whole-grain consumption may protect against type 2 diabetes.

Cardiovascular disease

A meta-analysis of 10 large prospective cohort studies published between 1998 and 2010 found that the highest intake of whole grains (about three servings daily) was associated with an overall 21% reduced risk of cardiovascular disease (CVD), including coronary heart disease (CHD), ischemic heart disease, heart failure, and ischemic stroke, when compared to the lowest intake of whole grains and after adjustment for several CVD risk factors (20). Further, although evidence is currently limited, whole-grain intake may be associated with a reduced risk of hypertension, a risk factor for cardiovascular disease (21, 22).

Compared to refined grains, whole grains are rich in nutrients associated with cardiovascular risk reduction. In the Health Professionals Follow-up Study (HPFS) in 42,850 men, the top versus bottom quintile (49.6 g/day vs. 3.3 g/day) of whole-grain intake was associated with a 16% reduced risk of CHD after multiple adjustments for age, gender, and CHD risk factors (23). Further adjustments for whole-grain constituents, such as fiber, folate, magnesium, manganese, vitamin B_6 and vitamin E, attenuated the association such that it was no longer statistically significant, suggesting that the micronutrient and fiber content may explain the cardiovascular benefits of consuming whole grains. Protective cardiovascular effects associated with higher intakes of whole grains and lower intakes of refined grains have included improvements in blood lipid profiles and reductions in markers of subclinical inflammation.

Whole grains and cardiometabolic markers

A meta-analysis of 21 randomized controlled trials indicated that whole-grain interventions for 4 to 16 weeks could improve an individual's blood concentrations of fasting glucose, insulin, total and LDL-cholesterol, as well as reduce diastolic and systolic blood pressure (20). Consistent with this, a recently updated meta-analysis of 23 randomized controlled trials published between 1988 and 2015 indicated that consumption of whole grains (28 g/day-213 g/day for 2 to 16 weeks), especially whole-grain oats in cereal and other products, for a couple of weeks resulted in significant reductions in blood concentrations of triglycerides and total and LDL-cholesterol when compared to control diets with refined grain (24). Interventions that included mixed whole-grain products (bread, muesli, ready-to-eat cereal, pasta, rice, crisps, muffins, cookies) also improved blood HDL-cholesterol concentrations (24). In addition, although wheat fiber has not been found to lower serum cholesterol concentrations, numerous clinical studies have demonstrated that increasing intakes of oat fiber and soluble fiber from barley resulted in modest reductions in total and LDL-cholesterol (25-27). In light of such findings, the US Food and Drug Administration (FDA) approved claims regarding whole grains and reduction in risk of CHD that apply to diets low in saturated fat and cholesterol providing at least 3 g/day of β-glucan soluble fiber from oats (oat bran, rolled oats [oatmeal], whole oat flour) or whole-grain barley (28). Whole grains are also sources of phytosterols — compounds that can decrease serum cholesterol by interfering with its intestinal absorption (2).

Whole grains and inflammation markers

Evidence from observational studies suggested an inverse association between whole-grain intake and chronic low-grade inflammation that characterizes cardiovascular and metabolic diseases (29). However, intervention studies have provided mixed results. In a recent cross-over trial in healthy low whole-grain consumers, the effect of increased consumption of mixed whole grains (mean intake, 168 g/day) for six weeks was compared to whole-grain consumption of less than 16 g/day. Increasing whole-grain intake had no effect on absolute counts of immune cells in blood (leukocytes, lymphocytes, natural killer cells), on *ex vivo* phagocytic activities of these cells, or on markers of inflammation (e.g., IL-10, TNF-α, C-reactive protein [CRP]) in blood (30). Previous randomized controlled studies in healthy normal weight, overweight, or obese subjects have also failed to demonstrate any benefits of whole-grain intake on markers of inflammation (31-35). One eight-week dietary intervention study in 80 overweight or obese subjects found that replacement of refined products in the habitual diet by whole-grain wheat products resulted in a significant reduction in pro-inflammatory cytokine TNF-α, a transient increase in anti-inflammatory IL-10, and no change in CRP compared to intake of refined wheat (36). In another randomized cross-over intervention study, overweight/obese children (ages, 8-15 years) were provided with a list of whole-grain products and asked to either obtain half of their grain servings from whole-grain foods every day for six weeks (whole-grain group) or abstain from consuming any of these foods (control group). Mean daily consumption of 98 g of whole-grain products (compared to 11 g/day) resulted in reductions in serum concentrations of CRP, sICAM-1 (soluble intercellular adhesion molecule-1), acute phase protein SAA (serum amyloid A), and leptin (37). An increased whole-grain intake to about five daily servings (compared to <1 serving/day) also reduced blood concentrations of CRP but had no effect on IL-10 and TNF-α concentrations in obese adults with metabolic syndrome following a hypocaloric diet (38). Inconsistency among studies may be attributed to differences in the health status of participants, the duration of interventions, and/or the types of whole grains selected. In particular, if foods with a low glycemic index (GI) can lower cardiometabolic and inflammation markers (39), substituting refined grain products by whole grains with high GI may not demonstrate any benefits regarding the risk of heart disease.

Cancer

Although the protective effects of whole grains against various types of cancer are not as well established as those against type 2 diabetes mellitus and cardiovascular disease, numerous case-control studies have found inverse associations between whole-grain intake and cancer risk (40-42). An early meta-analysis of 40 case-control studies examining 20 different types of cancer found that people with higher whole-grain intakes had an overall risk of cancer that was 34% lower than those with lesser whole-grain intakes (40). Higher intakes of whole grains were most consistently associated with decreased risk of gastrointestinal tract cancers, including cancers of the mouth, throat, esophagus, stomach, colon, and rectum. A prospective cohort study that followed more than 61,000 Swedish women for 15 years found that those who consumed more than 4.5 servings of whole grains daily had a 35% lower risk of colon cancer than those who consumed less than 1.5 servings of whole grains daily (43). In the large National Institutes of Health (NIH)-AARP Diet and Health prospective study in 291,988 men and 197,623 women, mean whole-grain intakes — much lower than in the above-mentioned Swedish cohort — were also inversely associated with risk of colorectal cancer, especially rectal cancer (44). Specifically, the highest versus lowest quintile of whole-grain intake (2.6 servings/day vs. 0.4 servings/day) was associated with a 36% lower risk of developing rectal cancer (44). In a nested case-control study, including participants of the multicenter European Prospective Investigation into Cancer and Nutrition (EPIC), the top versus bottom quartile of plasma alkylresorcinol concentrations, used as a surrogate marker of whole-grain wheat and rye intakes, was found to be associated with a 52% lower incidence of distal colon cancer. No correlations were reported with the incidence of rectal cancer, colon cancer, and proximal colon cancer, or with the overall incidence of colorectal cancers (45). Not all cohort studies have suggested that whole grains might protect against intestinal cancers (46, 47). However, a dose-response analysis based on the results of six cohort studies found a 17% reduction in colorectal cancer risk with an increment of three servings (three oz-eq or 90 g) of whole grains daily (48). Of note, a recent analysis of three Scandinavian cohorts that are also part of the EPIC study and include over 110,000 participants showed an inverse correlation between total whole-grain intake and esophageal cancer risk. Each 10 g-increase in whole-grain wheat intake was found to be associated with a 50% lower risk of esophageal cancer. Such an association was not observed with whole-grain rye or with whole-grain oats (49).

In contrast to refined-grain products, whole grains are rich in numerous compounds that may be protective against cancer, particularly cancers of the gastrointestinal tract (50). Whole grains are a major source of fiber, and high-fiber intakes are thought to speed up the passage of stool through the colon, allowing less time for potentially carcinogenic compounds to stay in contact with cells that line the inner surface of the colon (51). Dietary fiber can also exert chemopreventive effects via short-chain fatty acids that are generated when fiber is fermented by the colonic microbiota (52). Whole grains also contain compounds such as phenolic acids, lignans, phytoestrogens, flavonoids, and vitamin E, that may modify signal transduction pathways that promote the development of cancer or bind potentially damaging free metal ions in the gastrointestinal tract (53, 54).

Mortality

Recent large prospective cohort studies have investigated the relationship between whole-grain consumption and the risk of all-cause and cause-specific mortality. Higher versus lower intakes of whole grains (1.20 oz-eq/day versus 0.13 oz-eq/day) have been associated with a 17% lower risk of all-cause mortality in the NIH-AARP Diet and Health Study of 367,442 older adults (55). Higher whole-grain intakes were significantly associated with a decreased risk of mortality from cardiovascular disease (-17%), cancer (-15%), type 2 diabetes mellitus (-48%), respiratory disease (-11%), and infections (-23%). These associations were largely attenuated after adjustments for cereal fiber intakes, suggesting a major role for fiber in the protective effects of whole grains on mortality (55). Another recent analysis of two US prospective cohort studies, the Nurses' Health Study (NHS) in 74,341 women and the Health Professionals Follow-up Study (HPFS) in 43,744 men, reported a 9% lower risk of all-cause mortality in individuals in the highest versus lowest quintile of whole-grain intake (56). Higher whole-grain consumption was associated with a 15% lower risk of cardiovascular disease-related mortality, but no correlation was found with cancer-related mortality. Finally, the association of whole-grain intake with mortality was also examined in over 110,000 participants of the Scandinavian HELGA cohort (57). In this cohort, a doubling of the consumption of whole-grain products or that of specific whole-grain wheat, rye, or oats was associated with a reduced risk of all-cause and cause-specific mortality.

These results from cohort studies in the US and northern Europe consistently suggested a role of whole-grain consumption in the prevention of early death.

Intestinal health

Diets rich in whole grains and fiber may help prevent or improve constipation symptoms by softening and adding bulk to stool and by speeding its passage through the colon (58, 59). Such diets are also associated with decreased risk of diverticulosis, a condition characterized by the formation of small pouches (diverticula) in the colon. Although most people with diverticulosis experience no symptoms, about 10%-25% may develop pain or inflammation, known as diverticulitis (58). Diverticulitis was virtually unheard of before the practice of milling (refining) flour began in industrialized countries, and the role of a low-fiber diet in the development of diverticular disease is well established (60). If high-fiber diets reduce the risk of diverticular disease (61, 62), then the source of fiber (e.g., from cereal, fruit, vegetables) may be important. Interestingly, a 5 g-increase in intake of fiber from cereal was found to be associated with a 14% reduced risk of diverticular disease in a UK-based cohort of 690,075 women (mean age, 60 years) followed for up to six years; the risk of diverticular disease was decreased by 15% and 5% with a 5 g-increase in the consumption of fruit fiber and vegetable fiber, respectively (62). High-fiber diets are also recommended for people with diverticulosis in order to prevent the formation of additional diverticula rather than to resolve formed diverticula (58). People with diverticulosis are sometimes advised to avoid eating small seeds and husks to prevent them from becoming lodged in diverticula and causing diverticulitis, especially if they do not consume a high-fiber diet (58). However, it should be noted that no study has ever shown that avoiding seeds or popcorn reduces the risk of diverticulitis in an individual with diverticulosis (60).

Body weight management

Prospective cohort studies have consistently suggested that whole-grain consumption is associated with lower body mass index (BMI) and lower risks of weight gain and obesity (6, 20). However, a recent meta-analysis of randomized controlled trials published between 1988 and 2012 reported no significant effects of whole-grain intakes (from 18.2 g/day-150 g/day for 2 to 16 weeks) on body weight (26 trials), body fat (7 studies), and waist circumference (9 studies) in up to 2,060 normal-weight or overweight/obese adults without chronic health conditions (63). In a recent randomized, open-label, controlled trial in 60 overweight/obese individuals with metabolic syndrome, the consumption of whole grains (about 6-12 servings/day) was compared to that of refined grains during a 12-week intervention period that included a weight-maintenance diet for the first six weeks followed by six weeks of a hypocaloric diet (64). Increased whole-grain intake failed to lower body weight, BMI, percentage of body fat, or waist circumference beyond reductions also observed with consumption of refined grains. Of note, individuals who consumed whole grains showed an improved fasting glycemia compared to those fed refined grains, but other cardiometabolic variables remained unchanged (64). These results contrast with other energy-restricted dietary interventions showing a more favorable effect of whole grains on percentage of body fat compared to refined grains (38, 65). Further investigation is warranted to clarify whether whole-grain consumption could play a role in body weight regulation.

Intake Recommendations

Whole-grain intakes approaching three servings daily are associated with significant reductions in chronic disease risk in populations with relatively low whole-grain intakes. The 2015-2020 Dietary Guidelines for Americans — issued jointly by the US Department of Health and Human Services and US Department of Agriculture — recommend that at least half of all grains consumed be whole grains and to increase whole-grain intake by replacing refined grains with whole grains (66). In the 2015-2020 Dietary Guidelines for Americans, the unit of measure of a whole-grain serving size is the ounce-equivalent (oz-eq). A whole-grain serving size corresponds to (1) one ounce (~30 g) of a 100% whole-grain food in its ready-to-eat form, (2) two ounces of partly whole-grain products, or (3) the amount of food containing 16 g of whole-grain ingredients (67). **Table 1** summarizes the 2015-2020 US Dietary Guidelines for whole-grain intakes.

Table 1. 2015-2020 US Dietary Guideline Recommendations[1,2] for Whole-grain Intakes (according to 66)

Life Stage	Age	Daily Intake (oz-eq/day)[3]	Daily Intake (g/day)[4]
Children	2-3 years	1.5-2.5	24-40
Children	4-8 years	2-3	32-48
Children	9-13 years	2.5-4.5	40-72
Adolescents	14-18 years	3-5	48-80
Adults	19 years and older	3-5	48-80

[1] Dietary guidelines apply when no quantitative Dietary Reference Intake (DRI) value is available.
[2] The recommendations are based on estimated energy needs that vary with age and gender. Recommended daily intakes of whole grains at all calorie requirement levels can be found in the '2015-2020 Dietary Guidelines for Americans' report (see Appendix 3: Healthy US-style eating pattern) (66). For example, for 2,000 calories per day, the daily recommendation for whole-grain consumption is at least three ounce-equivalents or more per day (≥3 oz-eq).
[3] For example, one ounce-equivalent of whole grains can correspond to one ounce (~30 g) of a 100% whole-grain food or two ounces of partly whole-grain products.
[4] Daily intake of whole grains based on 100% whole-grain foods containing 16 grams of whole grains per ounce-equivalent (16 g/oz-eq).

The US National Health and Nutrition Examination Survey (NHANES) 2009-2010 reported mean whole-grain intakes of 0.57 oz-eq/day in children and adolescents and 0.82 oz-eq/day in adults (68). Approximately 40% of Americans consume no whole grains, and only 2.9% of children/adolescents and 7.7% of adults consume ≥3 oz-eq/day of whole grains (68). In view of the potential health benefits of increasing whole-grain intake, three daily servings of whole-grain foods should be seen as a minimum amount, and whole-grain foods should be substituted for refined carbohydrates whenever possible.

Examples of one serving of whole grains

- 1 slice of whole-grain bread
- ½ whole-grain English muffin, bagel, or bun
- 1 ounce of ready to eat whole-grain cereal
- ½ cup of oatmeal, brown rice, or whole-wheat pasta (cooked)
- 5-6 whole-grain crackers
- 1 tortilla (6" diameter)
- 1 pancake (5" diameter)

Increasing whole-grain intake

Finding whole-grain foods

Whole-grain foods may contain amaranth, whole-grain barley, brown and wild rice, buckwheat (kasha), millet, oats, popcorn, quinoa, whole rye, triticale, whole wheat (wheat berries) with various wheat species (including common wheat, emmer, spelt, and khorasan) (69). Unfortunately, it is not always clear from the label whether a product is made mostly from whole grains or refined grains. Some strategies to use when shopping for whole-grain foods include:

- Look for products that list whole grain(s) as the first ingredient(s).
- Look for whole-grain products that contain at least 2 grams of fiber per serving, since whole-grain foods are usually rich in fiber.
- Look for products that display the following health claim: "Diets rich in whole grain foods and other plant foods and low in total fat, saturated fat, and cholesterol may help reduce the risk of heart disease and certain cancers." Products displaying this health claim must contain at least 51% whole grain by weight or at least 8 grams of whole grains per ounce-equivalent (4).
- Look for whole-wheat pasta that lists whole-wheat flour as the first ingredient. Most pasta is made from refined semolina or durum wheat flour.
- Be aware that foods labeled with words like "multi-grain," "stone-ground," "100% wheat," "seven-grain," "cracked wheat," or "bran" are usually not 100% whole-grain products or can even be completely devoid of any whole grains (1).

Some strategies for increasing whole-grain intake

- Eat whole-grain breakfast cereal, such as wheat flakes, shredded wheat, muesli (rolled oats), and oatmeal. Bran cereal is not actually whole-grain cereal, but the high-fiber content makes it a good breakfast choice.
- Substitute whole-grain bread, rolls, tortillas, and crackers for those made from refined grains.
- Substitute whole-wheat pasta or pasta made from 50% whole wheat and 50% white flour for conventional pastas.
- Substitute brown rice for white rice.
- Add whole-grain barley to soups and stews.
- When baking, substitute whole-wheat flour (100% whole-wheat flour, white whole-wheat flour, or whole-wheat pastry flour) for white or unbleached flour.

Bioactive Components in Whole Grains

Whole grains are a source of numerous biologically active components; some are listed in **Table 2**.

Table 2. Some Potentially Beneficial Compounds in Whole Grains

Macronutrients	Vitamins	Minerals	Phytochemicals
Unsaturated Fats	Folate	Magnesium	Fiber
	Vitamin E	Potassium	Flavonoids
		Selenium	Lignans
			Phytosterols

Summary

- The glycemic index (GI) is a measure of the blood glucose-raising potential of the carbohydrate content of a food compared to a reference food (generally pure glucose). Carbohydrate-containing foods can be classified as high- (≥70), moderate- (56-69), or low-GI (≤55) relative to pure glucose (GI=100). *(More information)*
- Consumption of high-GI foods causes a sharp increase in postprandial blood glucose concentration that declines rapidly, whereas consumption of low-GI foods results in a lower blood glucose concentration that declines gradually. *(More information)*
- The glycemic load (GL) is obtained by multiplying the quality of carbohydrate in a given food (GI) by the amount of carbohydrate in a serving of that food. *(More information)*
- Prospective cohort studies found high-GI or -GL diets to be associated with a higher risk of adverse health outcomes, including type 2 diabetes mellitus and cardiovascular disease. *(More information)*
- Meta-analyses of observational studies have found little-to-no evidence of an association between high dietary GI and GL and risk of cancer. *(More information)*
- Lowering the GL of the diet may be an effective method to improve glycemic control in individuals with type 2 diabetes mellitus. This approach is not currently included in the overall strategy of diabetes management in the US. *(More information)*
- Several dietary intervention studies found that low-GI/GL diets were as effective as conventional, low-fat diets in reducing body weight. Both types of diets resulted in beneficial effects on metabolic markers associated with the risk of type 2 diabetes mellitus and cardiovascular disease. *(More information)*
- Lowering dietary GL can be achieved by increasing the consumption of whole grains, nuts, legumes, fruit, and non-starchy vegetables, and decreasing intakes of moderate- and high-GI foods like potatoes, white rice, white bread, and sugary foods. *(More information)*

Glycemic Index

Glycemic index of individual foods

In the past, carbohydrates were classified as simple or complex based on the number of simple sugars in the molecule. Carbohydrates composed of one or two simple sugars like fructose or sucrose (table sugar; a disaccharide composed of one molecule of glucose and one molecule of fructose) were labeled simple, while starchy foods were labeled complex because starch is composed of long chains of the simple sugar, glucose. Advice to eat less simple and more complex carbohydrates (i.e., polysaccharides) was based on the assumption that consuming starchy foods would lead to smaller increases in blood glucose than sugary foods (1). This assumption turned out to be too simplistic since the blood glucose (glycemic) response to complex carbohydrates has been found to vary considerably. The concept of glycemic index (GI) has thus been developed in order to rank dietary carbohydrates based on their overall effect on postprandial blood glucose concentration relative to a referent carbohydrate, generally pure glucose (2). The GI is meant to represent the relative quality of a carbohydrate-containing food. Foods containing carbohydrates that are easily digested, absorbed, and metabolized have a high GI (GI≥70 on the glucose scale), while low-GI foods (GI≤55 on the glucose scale) have slowly digestible carbohydrates that elicit a reduced postprandial glucose response. Intermediate-GI foods have a GI between 56 and 69 (3). The GI of selected carbohydrate-containing foods can be found in **Table 1**.

Measuring the glycemic index of foods

To determine the glycemic index (GI) of a food, healthy volunteers are typically given a test food that provides 50 grams (g) of carbohydrate and a control food (white, wheat bread or pure glucose) that provides the same amount of carbohydrate, on different days (4). Blood samples for the determination of glucose concentrations are taken prior to eating, and at regular intervals for a few hours after eating. The changes in blood glucose concentration over time are plotted as a curve. The GI is calculated as the incremental area under the glucose curve (iAUC) after the test food is eaten, divided by the corresponding iAUC after the control food (pure glucose) is eaten. The value is multiplied by 100 to represent a percentage of the control food (5):

$$\text{GI} = (\text{iAUC}_{\text{test food}}/\text{iAUC}_{\text{glucose}}) \text{ x } 100$$

For example, a boiled white potato has an average GI of 82 relative to glucose and 116 relative to white bread, which means that the blood glucose response to the carbohydrate in a baked potato is 82% of the blood glucose response to the same amount of carbohydrate in pure glucose and 116% of the blood glucose response to the same amount of carbohydrate in white bread. In contrast, cooked brown rice has an average GI of 50 relative to glucose and 69 relative to white bread. In the traditional system of classifying carbohydrates, both brown rice and potato would be classified as complex carbohydrates despite the difference in their effects on blood glucose concentrations.

While the GI should preferably be expressed relative to glucose, other reference foods (e.g., white bread) can be used for practical reasons as long as their preparation has been standardized and they have been calibrated against glucose (2). Additional recommendations have been suggested to improve the reliability of GI values for research, public health, and commercial application purposes (2, 6).

Physiological responses to high- versus low-glycemic index foods

By definition, the consumption of high-GI foods results in higher and more rapid increases in blood glucose concentrations than the consumption of low-GI foods. Rapid increases in blood glucose (resulting in hyperglycemia) are potent signals to the β-cells of the pancreas to increase insulin secretion (7). Over the next few hours, the increase in blood insulin concentration (hyperinsulinemia) induced by the consumption of high-GI foods may cause a sharp decrease in the concentration of glucose in blood (resulting in hypoglycemia). In contrast, the consumption of low-GI foods results in lower but more sustained increases in blood glucose and lower insulin demands on pancreatic β-cells (8).

Glycemic index of a mixed meal or diet

Many observational studies have examined the association between GI and risk of chronic disease, relying on published GI values of individual foods and using the following formula to calculate meal (or diet) GI (9):

$$\text{Meal GI} = [(\text{GI x amount of available carbohydrate})_{\text{Food A}} + (\text{GI x amount of available carbohydrate})_{\text{Food B}} + \ldots]/ \text{ total amount of available carbohydrate}$$

Yet, the use of published GI values of individual foods to estimate the average GI value of a meal or diet may be inappropriate because factors such as food variety, ripeness, processing, and cooking are known to modify GI values. In a study by Dodd et al., the estimation of meal GIs using published GI values of individual foods was overestimated by 22 to 50% compared to direct measures of meal GIs (9).

Besides the GI of individual foods, various food factors are known to influence the postprandial glucose and insulin responses to a carbohydrate-containing mixed diet. A recent cross-over, randomized trial in 14 subjects with type 2 diabetes mellitus examined the acute effects of four types of breakfasts with high- or low-GI and high- or low-fiber content on postprandial glucose concentrations. Plasma glucose was found to be significantly higher following consumption of a high-GI and low-fiber breakfast than following a low-GI and high-fiber breakfast. However, there was no significant difference in postprandial glycemic responses between high-GI and low-GI breakfasts of similar fiber content (10). In this study, meal GI values (derived from published data) failed to correctly predict postprandial glucose response, which appeared to be essentially influenced by the fiber content of meals. Since the amounts and types of carbohydrate, fat, protein, and other dietary factors in a mixed meal modify the glycemic impact of carbohydrate GI values, the GI of a mixed meal calculated using the above-mentioned formula is unlikely to accurately predict the postprandial glucose response to this meal (3). Moreover, the GI is a property of a given food carbohydrate such that it does not take into account individuals' characteristics like ethnicity, metabolic status, or eating habits (e.g., the degree to which we masticate) which might, to a limited extent, also influence the glycemic response to a given carbohydrate-containing meal (11-14).

Using direct measures of meal GIs in future trials — rather than estimates derived from GI tables — would increase the accuracy and predictive value of the GI method (2, 6). In addition, in a recent meta-analysis of 28 studies examining the effect of low- versus high-GI diets on serum lipids, Goff et al. indicated that the mean GI of low-GI diets varied from 21 to 57 across studies, while the mean GI of high-GI diets ranged from 51 to 75 (15). Therefore, a stricter use of GI cutoff values may also be warranted to provide more reliable information about carbohydrate-containing foods.

Glycemic Load

The glycemic index (GI) compares the potential of foods containing the same amount of carbohydrate to raise blood glucose. However, the amount of carbohydrate contained in a food serving also affects blood glucose concentrations and insulin responses. For example, the mean GI of watermelon is 76, which is as high as the GI of a doughnut (see **Table 1**). Yet, one serving of watermelon provides 11 g of available carbohydrate, while a medium doughnut provides 23 g of available carbohydrate.

The concept of glycemic load (GL) was developed by scientists to simultaneously describe the quality (GI) and quantity of carbohydrate in a food serving, meal, or diet. The GL of a single food is calculated by multiplying the GI by the amount of carbohydrate in grams (g) provided by a food serving and then dividing the total by 100 (4):

$$\text{GL}_{\text{Food}} = (\text{GI}_{\text{Food}} \text{ x amount (g) of available carbohydrate}_{\text{Food}} \text{ per serving})/100$$

For a typical serving of a food, GL would be considered high with GL≥20, intermediate with GL of 11-19, and low with GL≤10. Using the above-mentioned example, despite similar GIs, one serving of watermelon has a GL of 8, while a medium-sized doughnut has a GL of 17. Dietary GL is the sum of the GLs for all foods consumed in the diet.

It should be noted that while healthy food choices generally include low-GI foods, this is not always the case. For example, intermediate-to-high-GI foods like parsnip, watermelon, banana, and pineapple, have low-to-intermediate GLs (see **Table 1**).

Disease Prevention

Type 2 diabetes mellitus

The consumption of high-GI and -GL diets for several years might result in higher postprandial blood glucose concentration and excessive insulin secretion. This might contribute to the loss of the insulin-secreting function of pancreatic β-cells and lead to irreversible type 2 diabetes mellitus (16).

A US ecologic study of national data from 1909 to 1997 found that the increased consumption of refined carbohydrates in the form of corn syrup, coupled with the declining intake of dietary fiber, has paralleled the increased prevalence of type 2 diabetes (17). In addition, high-GI and -GL diets have been associated with an increased risk of type 2 diabetes in several large prospective cohort studies. A recent updated analysis of three large US cohorts indicated consumption of foods with the highest versus lowest GI was associated with a risk of developing type 2 diabetes that was increased by 44% in the Nurses' Health Study (NHS) I, 20% in the NHS II, and 30% in the Health Professionals Follow-up Study (HPFS). High-GL diets were associated with an increased risk of type 2 diabetes (+18%) only in the NHS I and in the pooled analysis of the three studies (+10%) (18). Additionally, the consumption of high-GI foods that are low in cereal fiber was associated with a 59% increase in diabetes risk compared to low-GI and high-cereal-fiber foods. High-GL and low-cereal-fiber diets were associated with a 47% increase in risk compared to low-GL and high-cereal-fiber diets. Moreover, obese participants who consumed foods with high-GI or -GL values had a risk of developing type 2 diabetes that was more than 10-fold greater than lean subjects consuming low-GI or -GL diets (18).

However, a number of prospective cohort studies have reported a lack of association between GI or GL and type 2 diabetes (19-24). The use of GI food classification tables based predominantly on Australian and American food products might be a source of GI value misassignment and partly explain null associations reported in many prospective studies of European and Asian cohorts.

Nevertheless, conclusions from several recent meta-analyses of prospective studies (including the above-mentioned studies) suggest that low-GI and -GL diets might have a modest but significant effect in the prevention of type 2 diabetes (18, 25, 26). Organizations like Diabetes UK (27) and the European Association for the Study of Diabetes (28) have included the use of diets of low GI/GL and high in dietary fiber and whole grains in their recommendations for diabetes prevention in high-risk individuals. The use of GI and GL is currently not implemented in US dietary guidelines (29).

Cardiovascular disease

Observational studies

Numerous observational studies have examined the relationship between dietary GI/GL and the incidence of cardiovascular events, especially coronary heart disease (CHD) and stroke. A meta-analysis of 14 prospective cohort studies (229,213 participants; mean follow-up of 11.5 years) found a 13% and 23% increased risk of cardiovascular disease (CVD) with high versus low dietary GI and GL, respectively (30). Three independent meta-analyses of prospective studies also reported that higher GI or GL was associated with increased risk of CHD in women but not in men (31-33). A recent analysis of the European Prospective Investigation into Cancer and Nutrition (EPIC) study in 20,275 Greek participants, followed for a median of 10.4 years, showed a significant increase in CHD incidence and mortality with high dietary GL specifically in those with high BMI (≥28 kg/m²) (34). This is in line with earlier findings in the Nurses' Health Study (NHS) showing that a high dietary GL was associated with a doubling of the risk of CHD over 10 years in women with higher (≥23 kg/m²) vs. lower BMI (35). A similar finding was reported in a cohort of middle-aged Dutch women followed for nine years (36).

Additionally, high dietary GL (but not GI) was associated with a 19% increased risk of stroke in pooled analyses of prospective cohort studies (32, 37). A meta-analysis of seven prospective studies (242,132 participants; 3,255 stroke cases) found that dietary GL was associated with an overall 23% increase in risk of stroke and a specific 35% increase in risk of ischemic stroke; GL was not found to be related to hemorrhagic stroke (38).

Overall, observational studies have found that higher glycemic load diets are associated with increased risk of cardiovascular disease, especially in women and in those with higher BMIs.

GI/GL and cardiometabolic markers

The GI/GL of carbohydrate foods may modify cardiometabolic markers associated with CVD risk. A meta-analysis of 27 randomized controlled trials (published between 1991 and 2008) examining the effect of low-GI diets on serum lipid profile reported a significant reduction in total and LDL-cholesterol independent of weight loss (15). Yet, further analysis suggested significant reductions in serum lipids only with the consumption of low-GI diets with high fiber content. In a three-month, randomized controlled study, an increase in the values of flow-mediated dilation (FMD) of the brachial artery, a surrogate marker of vascular health, was observed following the consumption of a low- versus high-GI hypocaloric diet in obese subjects (39).

High dietary GLs have been associated with increased concentrations of markers of systemic inflammation, such as C-reactive protein (CRP), interleukin-6, and tumor necrosis factor-α (TNF-α) (40, 41). In a small 12-week dietary intervention study, the consumption of a Mediterranean-style, low-GL diet (without caloric restriction) significantly reduced waist circumference, insulin resistance, systolic blood pressure, as well as plasma fasting insulin, triglycerides, LDL-cholesterol, and TNF-α in women with metabolic syndrome. A reduction in the expression of the gene coding for 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase, the rate-limiting enzyme in cholesterol synthesis, in blood cells further confirmed an effect for the low-GI diet on cholesterol homeostasis (42). Well-controlled, long-term intervention studies are needed to confirm the potential cardiometabolic benefits of low GI/GL diets in people at risk for CVD.

Cancer

Evidence that high-GI or -GL diets are related to cancer is inconsistent. A recent meta-analysis of 32 case-control studies and 20 prospective cohort studies found modest and nonsignificant increased risks of hormone-related cancers (breast, prostate, ovarian, and endometrial cancers) and digestive tract cancers (esophageal, gastric, pancreas, and liver cancers) with high versus low dietary GI and GL (43). A significant positive association was found only between a high dietary GI and colorectal cancer (43). Yet, earlier meta-analyses of prospective cohort studies failed to find a link between high-GI or -GL diets and colorectal cancer (44-46). Another recent meta-analysis of prospective studies suggested a borderline increase in breast cancer risk with high dietary GI and GL. Adjustment for confounding factors across studies found no modification of menopausal status or BMI on the association (47). Further investigations are needed to verify whether GI and GL are associated with various cancers.

Gallbladder disease

Results of two studies indicate GI and GL may be related to gallbladder disease: a higher dietary GI and GL were associated with significantly increased risks of developing gallstones in a cohort of men participating in the Health Professionals Follow-up Study (48) and in a cohort of women participating in the Nurses' Health Study (49). However, more epidemiological research is needed to determine an association between dietary glycemic index/load and gallbladder disease.

Disease Treatment

Diabetes mellitus

Whether low-GI foods could improve overall blood glucose control in people with type 1 or type 2 diabetes mellitus has been investigated in a number of intervention studies. A meta-analysis of 19 randomized controlled trials that included 840 diabetic patients (191 with type 1 diabetes and 649 with type 2 diabetes) found that consumption of low-GI foods improved short-term and long-term control of blood glucose concentrations, reflected by significant decreases in fructosamine and glycated hemoglobin (HbA1c) levels (50). However, these results need to be cautiously interpreted because of significant heterogeneity among the included studies. The American Diabetes Association has rated poorly the current evidence supporting the substitution of low-GL foods for high-GL foods to improve glycemic control in adults with type 1 or type 2 diabetes (51, 52). Well-controlled studies are needed to further assess whether the use of low-GI/GL diets could significantly improve long-term glycemic control and the quality of life of subjects with diabetes.

A randomized controlled study in 92 pregnant women (20-32 weeks) diagnosed with gestational diabetes found no significant effects of a low-GI diet on maternal metabolic profile (e.g., blood concentrations of glucose, insulin, fructosamine, HbA1c; insulin resistance) and pregnancy outcomes (i.e., maternal weight gain and neonatal anthropometric measures) compared to a conventional high-fiber, moderate-GI diet (53). The low-GI diet consumed during the pregnancy also failed to improve maternal glucose tolerance, insulin sensitivity, and other cardiovascular risk factors, or maternal and infant anthropometric data in a three-month postpartum follow-up study of 55 of the mother-infant pairs (54). In addition, another trial in 139 pregnant women (12-20 weeks' gestation) at high risk for gestational diabetes showed no statistical differences regarding the diagnosis of gestational diabetes during the second and third trimester of pregnancy, the requirement for insulin therapy, and pregnancy outcomes and neonatal anthropometry whether women followed a low-GI diet or a high-fiber, moderate-GI diet (55). At present, there is no evidence that a low-GI diet provides benefits beyond those of a healthy, moderate-GI diet in women at high risk or affected by gestational diabetes.

Obesity

Obesity is often associated with metabolic disorders, such as hyperglycemia, insulin resistance, dyslipidemia, and hypertension, which place individuals at increased risk for type 2 diabetes mellitus, cardiovascular disease, and early death (56, 57). Traditionally, weight-loss strategies have included energy-restricted, low-fat, high-carbohydrate diets with >50% of calories from carbohydrates, ≤30% from fat, and the remainder from protein. However, a recent meta-analysis of randomized controlled intervention studies (≥6 months' duration) has reported that low- or moderate-carbohydrate diets (4%-45% carbohydrate) and low-fat diets (10%-30% fat) were equally effective at reducing body weight and waist circumference in overweight or obese subjects (58).

Low-GI/GL diet versus moderate-GI/GL, low-fat diet

Several dietary intervention studies have examined how low-GI/GL diets compared with conventional low-fat diets to promote weight loss. Lowering the GI of conventional energy-restricted, low-fat diets was proven to be more effective to reduce postpartum body weight and waist and hip circumferences and prevent type 2 diabetes mellitus in women with prior gestational diabetes mellitus (59). In a six-month dietary intervention study in 73 obese adults, no differences in weight loss were reported in subjects following either a low-GL diet (40% carbohydrate and 35% fat) or a low-fat diet (55% carbohydrate and 20% fat). Yet, the consumption of a low-GL diet increased HDL-cholesterol and decreased triglyceride concentrations significantly more than the low-fat diet, but LDL-cholesterol concentration was significantly more reduced with the low-fat than low-GI diet (60).

A one-year randomized controlled study of 202 individuals with a body mass index (BMI) ≥28 and at least another metabolic disorder compared the effect of two dietary counseling-based interventions advocating either for a low-GL diet (30%-35% of calories from low-GI carbohydrates) or a low-fat diet (<30% of calories from fat) (61). Weight loss with each diet was equivalent (~4 kg). Both interventions similarly reduced triglycerides, C-reactive protein (CRP), and fasting insulin, and increased HDL-cholesterol. Yet, the reduction in waist and hip circumferences was greater with the low-fat diet, while blood pressure was significantly more reduced with the low-GL diet (61). In the GLYNDIET study, a six-month randomized dietary intervention trial, the comparison of two moderate-carbohydrate diets (42% of calories from carbohydrates) with different GIs (GI of 34 or GI of 62) and a low-fat diet (30% of calories from fat; GI of 65) on weight loss indicated that the low-GI diet reduced body weight more effectively than the low-fat diet. Additionally, the low-GI diet improved fasting insulin concentration, β-cell function, and insulin resistance better than the low-fat diet. None of the diets modulated hunger or satiety or affected biomarkers of endothelial function or inflammation. Finally, no significant differences were observed in low- compared to high-GL diets regarding weight loss and insulin metabolism (62).

Low-GI/GL diet versus high-GI/GL diet

In a meta-analysis of 14 randomized controlled trials published between 2005 and 2011, neither high- nor low-GI/GL dietary interventions conducted for 6 to 17 months had any significant effect on body weight and waist circumference in a total of 2,344 overweight and obese subjects (63). Low-GI/GL diets were found to significantly reduce C-reactive protein and fasting insulin but had no effect on blood lipid profile, fasting glucose concentration, or HbA1c concentration compared to high-GI/GL diets.

It has been suggested that the consumption of low-GI foods delayed the return of hunger, decreased subsequent food intake, and increased satiety when compared to high-GI foods (64). The effect of isocaloric low- and high-GI test meals on the activity of brain regions controlling appetite and eating behavior was evaluated in a small randomized, blinded, cross-over study in 12 overweight or obese men (65). During the postprandial period, blood glucose and insulin rose higher after the high-GI meal than after the low-GI meal. In addition, in response to the excess insulin secretion, blood glucose dropped below fasting concentrations three to five hours after high-GI meal consumption. Cerebral blood flow was significantly higher four hours after ingestion of the high-GI meal (compared to a low-GI meal) in a specific region of the striatum (right nucleus accumbens) associated with food intake reward and craving. If the data suggested that consuming low- rather than high-GI foods may help restrain overeating and protect against weight gain, this has not yet been confirmed in long-term randomized controlled trials. In the recent multicenter, randomized controlled Diet, Obesity, and Genes (DiOGenes) study in 256 overweight and obese individuals who lost ≥8% of body weight following an eight-week calorie-restricted diet, consumption of *ad libitum* diets with different protein and GI content for 12 months showed that only high-protein diets — regardless of their GI — could mitigate weight regain (66). However, the dietary interventions only achieved a modest difference in GI (~5 units) between high- and low-GI diets such that the effect of GI in weight maintenance remained unknown.

Lifestyle modification programs do not currently include the reduction of calories from carbohydrate as an alternative to standard prescription of low-fat diets, nor do they suggest the use of GI/GL as a guide to healthier dietary choices (67).

Lowering Dietary Glycemic Load

Some strategies for lowering dietary GL include:

- Increasing the consumption of whole grains, nuts, legumes, fruit, and non-starchy vegetables
- Decreasing the consumption of starchy, moderate- and high-GI foods like potatoes, white rice, and white bread
- Decreasing the consumption of sugary foods like cookies, cakes, candy, and soft drinks

Table 1 includes GI and GL values of selected foods relative to pure glucose (68). Foods are ranked in descending order of their GI values, with high-GI foods (GI≥70) at the top and foods with low-GI values (≤55) at the bottom of the table. To look up the GI values for other foods, visit the University of Sydney's GI website.

Table 1. GI and GL Values for Selected Foods

Food	GI (Glucose=100)	Serving Size	Carbohydrate* per Serving (g)	GL per Serving
Russet potato, baked	111	1 medium	30	33
Potato, white, boiled (average)	82	1 medium	30	25
Puffed rice cakes	82	3 cakes	21	17
Cornflakes	79	1 cup	26	20
Jelly beans	78	1 oz	28	22
Doughnut	76	1 medium	23	17
Watermelon	76	1 cup	11	8
Soda crackers	74	4 crackers	17	12
Bread, white-wheat flour	71	1 large slice	14	10
Pancake	67	6" diameter	58	39
Rice, white, boiled	66	1 cup	53	35
Table sugar (sucrose)	63	2 tsp	10	6
Dates, dried	62	2 oz	40	25
Spaghetti, white, boiled (20 min)	58	1 cup	44	25
Honey, pure	58	1 Tbsp	17	10
Pineapple, raw	58	½ cup	19	11
Banana, raw	55	1 cup	24	13
Maple syrup, Canadian	54	1 Tbsp	14	7
Parsnips, peeled, boiled	52	½ cup	10	5
Rice, brown, boiled	50	1 cup	42	20
Spaghetti, white, boiled (average)	46	1 cup	44	20
Whole-grain pumpernickel bread	46	1 large slice	12	5
All-Bran™ cereal	45	1 cup	21	10
Spaghetti, whole-meal, boiled	32	1 cup	37	14
Orange, raw	42	1 medium	11	5

Apple, raw	39	1 medium	15	6
Pear, raw	38	1 medium	11	4
Skim milk	33	8 fl oz	13	4
Carrots, boiled	33	½ cup	4	1
Lentils, dried, boiled	29	1 cup	24	7
Kidney beans, dried, boiled	28	1 cup	29	8
Pearled barley, boiled	28	1 cup	38	11
Cashews	25	1 oz	9	2
Peanuts	18	1 oz	6	1

*Amount of available carbohydrates in a food serving that excludes indigestible carbohydrates, i.e., dietary fiber.

Summary

- Coffee is a complex mixture of chemicals that provides significant amounts of chlorogenic acid and caffeine. *(More information)*
- Unfiltered coffee is a significant source of diterpenes (mainly cafestol and kahweol) that appear to raise serum total and LDL-cholesterol concentrations in humans. *(More information)*
- The results of observational studies suggest that coffee consumption is associated with lower risks of type 2 diabetes mellitus, Parkinson's disease, liver disease, and mortality. However, it is premature to recommend coffee consumption for disease prevention based on this evidence. *(More information)*
- Coffee consumption has been associated with lower risks of cirrhosis, cirrhosis-related mortality, and liver cancer. Coffee consumption was also found to be inversely associated with the risk of oral/pharyngeal cancer, colon cancer, prostate cancer, endometrial cancer, and melanoma. Evidence also suggests that coffee consumption is not a risk factor for lung cancer. *(More information)*
- Despite evidence from clinical trials that caffeine in coffee can increase blood pressure, most prospective cohort studies have not found moderate coffee consumption to be associated with increased risk of cardiovascular disease. *(More information)*
- Caffeine intake comparable to the amount in 2-3 cups of coffee may raise blood pressure, especially in people with borderline or high blood pressure. However, regular coffee consumption in hypertensive subjects has not been associated with an increased risk of cardiovascular disease. *(More information)*
- Current evidence from dose-response meta-analyses of observational studies does not exclude that moderate maternal coffee consumption could adversely affect fetal growth during pregnancy. Limiting intakes of caffeinated coffee to ≤1 cup/day during pregnancy and 2-3 cups/day during breast-feeding is recommended. *(More information)*
- Ensuring adequate calcium and vitamin D intakes and limiting coffee consumption to 3 cups/day (~300 mg/day of caffeine) are unlikely to cause any adverse effects on calcium absorption and bone health. *(More information)*
- Overall, there is little evidence of health risks and some evidence of health benefits for adults consuming moderate amounts of filtered coffee (3-4 cups/day providing ~300-400 mg/day of caffeine). *(More information)*

Introduction

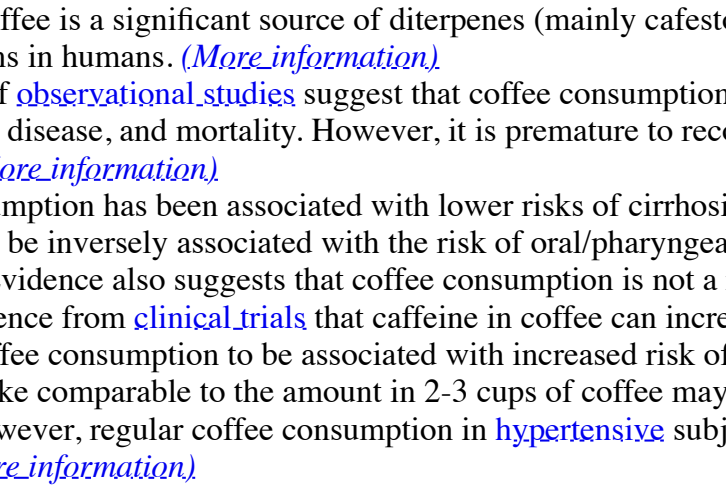
Coffee, an infusion of ground, roasted coffee beans, is among the most widely consumed beverages in the world. The main types of coffee consumed are (1) boiled unfiltered coffee, (2) filtered coffee, and (3) decaffeinated coffee (1). Although caffeine has received the most attention from scientists, coffee is a complex mixture of many chemicals, including carbohydrates, lipids (fats), amino acids, vitamins, minerals, alkaloids, and phenolic compounds (2). The composition of coffee varies with the source of coffee beans (*Coffea arabica* or *Coffea canephora* var. *robusta*) (3), as well as with the method of preparation (i.e., filtration methods, boiling, steeping, or brewing under pressure) (1, 4).

Some Bioactive Compounds in Coffee

Chlorogenic acids

Chlorogenic acids are a family of esters formed between quinic acid and phenolic compounds known as cinnamic acids (mostly caffeic acid and ferulic acid) (1). The most abundant chlorogenic acid in coffee is 5-*O*-caffeoylquinic acid, an ester formed between quinic acid and caffeic acid (**Figure 1**). Coffee represents one of the richest dietary sources of chlorogenic acids. The chlorogenic acid content of a 200 mL (7-oz) cup of coffee has been reported to range from 70 to 350 mg, which would provide about 35 to 175 mg of caffeic acid. Although chlorogenic and caffeic acids have demonstrated antioxidant activities *in vitro* (5), it is unclear how much antioxidant activity they contribute *in vivo* because they are extensively metabolized, and the metabolites often have lower antioxidant activity than the parent compounds (6, 7). Additionally, the antioxidant capacity of coffee is attenuated by the decaffeination process, which decreases total polyphenol content (8). Other phenolic compounds in coffee, though less abundant than chlorogenic acids, include tannins, lignans, and anthocyanine (1).

Figure 1. Chemical Structure of a Chlorogenic Acid



5-*O*-caffeoylquinic acid

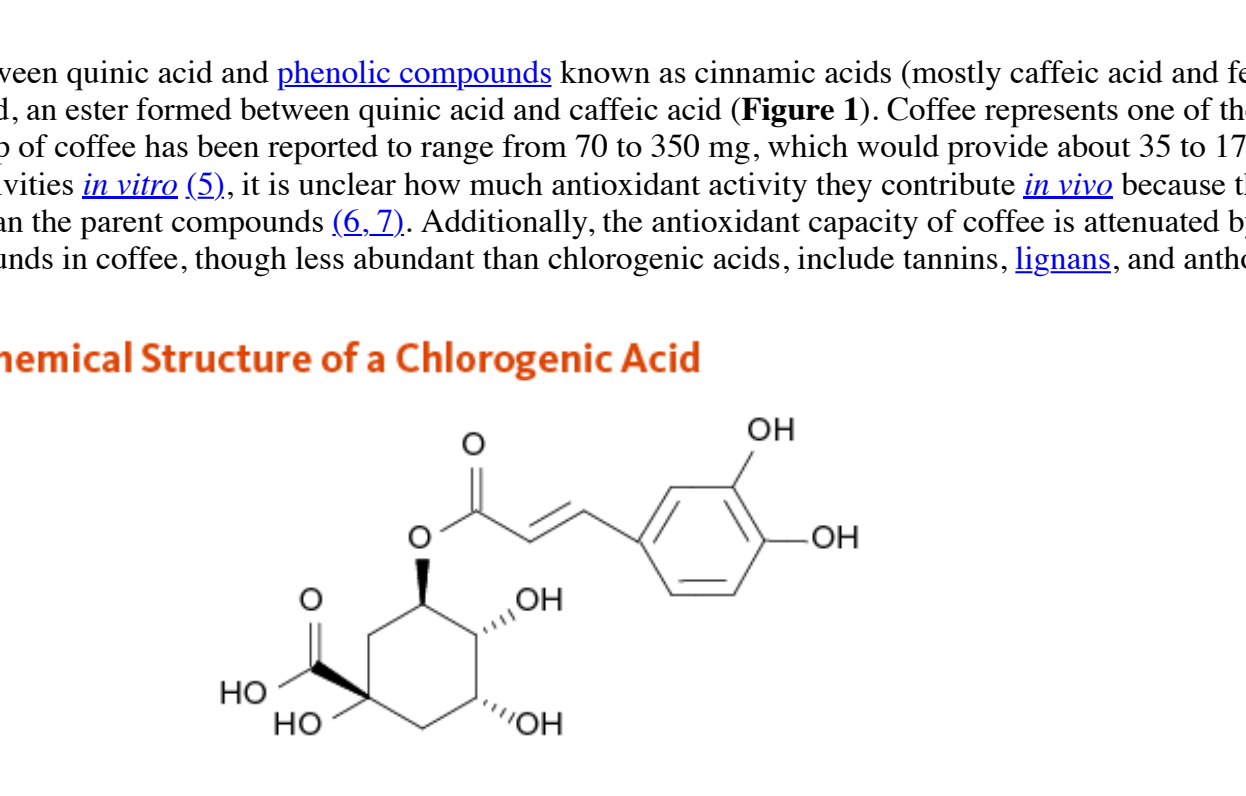
Caffeine

Caffeine (1,3,7-trimethylxanthine) is a purine alkaloid that occurs naturally in coffee beans (**Figure 2**). At intake levels associated with coffee consumption, caffeine appears to exert most of its biological effects through antagonism of the A$_1$ and A$_{2A}$ subtypes of the adenosine receptor (1). Adenosine is an endogenous compound that modulates the response of neurons to neurotransmitters. Adenosine has mostly inhibitory effects in the central nervous system, so the effects of adenosine antagonism by caffeine are generally stimulatory. Caffeine is rapidly and almost completely absorbed in the stomach and small intestine and then distributed to all tissues, including the brain. Caffeine concentrations in coffee beverages can be quite variable. A standard cup of coffee is often assumed to provide 100 mg of caffeine, but an analysis of 14 different specialty coffees purchased at coffee shops in the US found that the amount of caffeine in 8 oz (~240 mL) of brewed coffee ranged from 72 to 130 mg (9). Caffeine in espresso coffees ranged from 58 to 76 mg in a single shot (~35 to 50 mL). In countries other than the US, coffee is often stronger, but the volume per cup is smaller, making 100 mg of caffeine/cup a reasonable estimate.

Figure 2. Chemical Structures of Caffeine and Adenosine

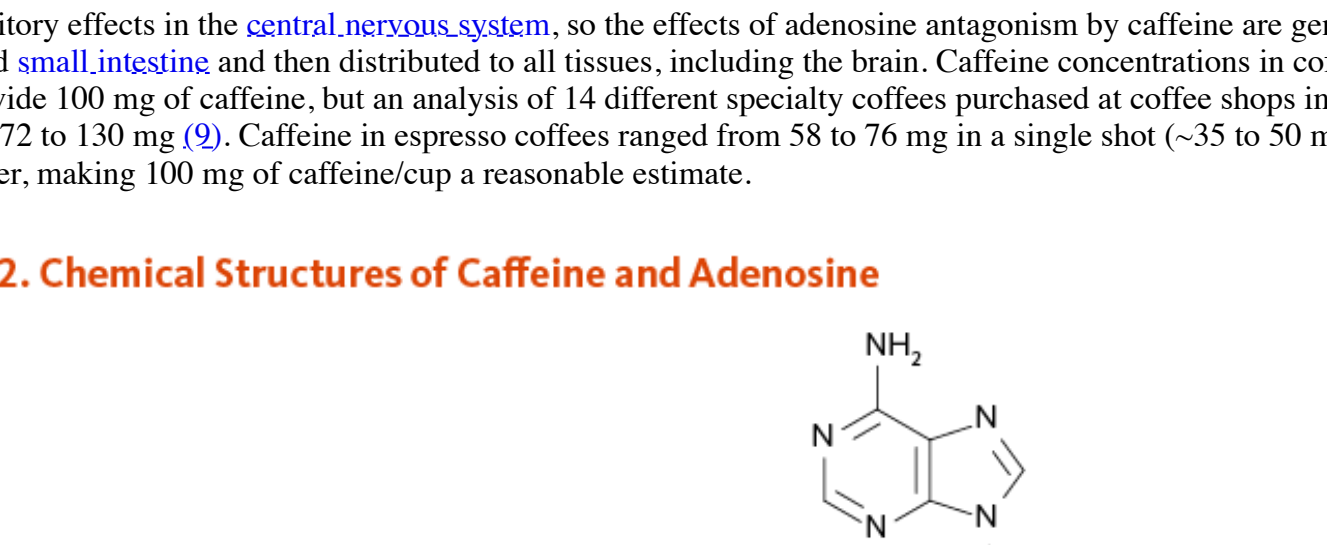


[Figure 2 - Click to Enlarge]

Diterpenes

Cafestol and kahweol are fat-soluble compounds known as diterpenes (**Figure 3**), which have been found to raise serum total and LDL-cholesterol concentrations in humans (10). Some cafestol and kahweol are extracted from ground coffee during brewing, but are largely removed from coffee by paper filters. Scandinavian boiled coffee, Turkish coffee, and French press (cafetiere) coffee contain relatively high levels of cafestol and kahweol (6 to 12 mg/cup), while filtered coffee, percolated coffee, and instant coffee contain low levels of cafestol and kahweol (0.2 to 0.6 mg/cup) (11). Although diterpene concentrations are relatively high in espresso coffee, the small serving size makes it an intermediate source of cafestol and kahweol (4 mg/cup). Since coffee beans are high in cafestol and kahweol, ingestion of coffee beans or grounds on a regular basis may also raise serum total and LDL-cholesterol.

Figure 3. Chemical Structures of Two Diterpenes



Free diterpene: R=H
Diterpene ester: R=fatty acid

[Figure 3 - Click to Enlarge]

Trigonelline

Trigonelline (*N*-methylnicotinic acid) is a plant alkaloid derived from niacin (vitamin B$_3$) (**Figure 4**). Trigonelline is largely broken down to nicotinic acid during the roasting process, although some intact molecules remain in roasted beans. Trigonelline has been found to exert antioxidant, hypoglycemic, and hypolipidemic activities (reviewed in 1).

Disease Prevention

Type 2 diabetes mellitus

Observational studies

The three largest prospective cohort studies in the US to examine the relationship between caffeinated coffee consumption and type 2 diabetes mellitus were the Health Professionals Follow-up Study ([HPFS]; 41,934 men), the Nurses' Health Study ([NHS I]; 84,276 women), and the NHS II (88,259 women). Men who drank at least six cups of coffee daily had a 54% lower risk of developing type 2 diabetes than men who did not drink coffee. In the NHS I cohort, women who drank at least six cups of coffee daily had a 29% lower risk of type 2 diabetes than women who did not drink coffee (12). In the NHS II cohort, women who consumed ≥4 cups of coffee daily had a 39% lower risk of developing type 2 diabetes; similar results were found in women who drank 2 to 3 cups/day of coffee (13). In a pooled analysis of all three cohorts, an increase in caffeinated coffee intake by >1 cup/day over a four-year period was associated with a 13% decreased risk of type 2 diabetes in the subsequent four years; those who decreased their intake of caffeinated coffee by >1 cup/day had a 20% increased risk of type 2 diabetes over the four-year period (14).

Several other cohort studies have found higher coffee intakes to be associated with significant reductions in the risk of type 2 diabetes. A systematic review and meta-analysis of 18 prospective cohort studies (published between 1966 and 2009), including more than 450,000 men and women, found that the risk of developing type 2 diabetes was 24% lower in those consuming 3 to 4 cups/day of coffee compared to those consuming ≤2 cups/day or none (15). Two additional meta-analyses that included data from more recent prospective cohort studies were published concomitantly and found similar results (16, 17). The data analysis of 28 prospective studies in over 1 million participants with 45,335 incident cases of diabetes reported a 30% decreased risk of type 2 diabetes with coffee intake of 5 cups/day versus 0 cups/day (16). In addition, a 9% reduction in the incidence of type 2 diabetes was estimated for every one cup per day increase in total coffee intake. Likewise, a dose-response analysis of 11 studies found a 6% reduction in type 2 diabetes incidence for every one cup per day increase in decaffeinated coffee intake. Every 140 mg/day (~1 cup/day of coffee) increment in caffeine intake was also associated with an 8% reduction in the risk of type 2 diabetes (16). Although decaffeinated coffee consumption is associated with a more modest decrease in the risk of type 2 diabetes, it is likely that compounds other than caffeine contribute to the reduction in diabetes risk.

Intervention studies

The mechanisms that might contribute to the association between coffee consumption and lower risk of type 2 diabetes in prospective cohort studies are unclear. Bioactive compounds other than caffeine appear to show temporary hypoglycemic effects. For example, the acute ingestion of chlorogenic acid (1 g) and trigonelline (0.5 g) transiently lowered blood glucose concentration shortly after the administration of 75 g of glucose in an oral glucose tolerance test (18). Conversely, short-term clinical trials have found that acute administration of caffeine (3 to 6 mg/kg) impaired glucose tolerance and decreased insulin sensitivity in healthy participants (19). In addition, incremental doses of decaffeinated coffee (1, 2, and 4 servings) failed to lower postprandial blood glucose in the presence of 100 mg of caffeine (20). However, despite the deleterious effect of caffeine on glucose homeostasis, caffeinated coffee consumption may favorably affect other metabolic pathways. In a single-blinded clinical trial, subjects at risk for type 2 diabetes abstained from drinking caffeinated coffee for one month, then consumed 4 cups/day of coffee for another month, and finally consumed 8 cups/day for a third month. Compared to one month of coffee abstinence, the consumption of 8 cups/day of coffee for one month appeared to increase antioxidant capacity and reduce subclinical inflammation, as indicated by changes in plasma markers of oxidative stress and inflammation (21).

Until the relationship between long-term coffee consumption and type 2 diabetes risk is better understood, it is premature to recommend coffee consumption as a means of preventing type 2 diabetes (12, 22).

Parkinson's disease

Studies in animal models of Parkinson's disease suggest that caffeine may protect dopaminergic neurons by acting as an adenosine A$_{2A}$-receptor antagonist in the brain (23). Several large prospective cohort studies have examined coffee and/or caffeine intakes in association with Parkinson's disease risk. A meta-analysis of nine prospective cohort studies found higher caffeine intake to be associated with significant reductions in Parkinson's disease risk in both men (-39%) and women (-29%) (24). In another meta-analysis of six case-control studies and seven prospective studies, including 901,764 participants and 3,954 cases, an inverse association between coffee intake and Parkinson's disease risk — only significant in men — was found to be nonlinear, with no further risk reduction beyond 3 to 4 cups/day of coffee. This meta-analysis also reported significant reductions in Parkinson's disease risk in men (-43%) and women (-36%) with the highest (700 mg/day) versus lowest (100 mg/day) intake of caffeine (25).

However, while prospective studies have consistently found a lower risk of developing Parkinson's disease with higher coffee and caffeine intakes in men, such an association has not always been observed in women (26-28). It is hypothesized that estrogen replacement therapy may modify the interaction between caffeine and risk of Parkinson's disease in postmenopausal women. Indeed, because estrogen and caffeine are metabolized by hepatic cytochrome P450 (CYP) 1A2 in the body, estrogen might compete for CYP1A2 activity and hinder the metabolism of caffeine in estrogen users (29). An analysis of data from more than 77,000 female nurses, followed for 18 years in NHS I, revealed that coffee consumption was inversely associated with Parkinson's disease risk in women who had never used postmenopausal estrogen (30). However, drinking ≥6 cups of coffee was associated with an increased risk or Parkinson's disease in women who had used postmenopausal estrogen (30). In a prospective cohort study that included more than 238,000 women, a significant inverse association between coffee consumption and Parkinson's disease mortality was also observed in women who had never used postmenopausal estrogen, but not in those who had used postmenopausal estrogen (31). Yet, in a recent analysis of the National Institutes of Health (NIH)-AARP Diet and Health Study, which included 303,880 participants and 1,100 cases, the highest versus lowest intake of caffeine was associated with a reduced risk of Parkinson's disease in postmenopausal women who ever used hormones but not among never users (24).

At present, it remains unclear whether caffeine consumption can prevent Parkinson's disease, particularly in women taking estrogen. Of note, whether caffeine could help reduce some common symptoms associated with Parkinson's disease (e.g., sleepiness, freezing of gait) is under investigation (32, 33).

Cognitive decline and dementia

Results from observational studies regarding a possible link between coffee consumption and cognitive disorders are inconclusive. A recent meta-analysis of nine prospective cohort studies in 34,282 older adults reported an 18% reduced risk of cognitive disorders with 1 to 2 cups/day of coffee compared to <1 cup/day (34). Yet, there was no difference in risk of cognitive disorders between daily coffee intakes >3 cups and <1 cup (34). Two other meta-analyses of prospective studies failed to find an association between high versus low intakes of coffee and risk of cognitive disorders (35, 36). No dose-response relationship was reported between coffee intake and risk of cognitive disorders (36).

Whether moderate coffee intake may reduce the risk of cognitive decline and dementia later in life is still not known.

Cirrhosis and liver cancer

Chronic inflammation-inducing liver injury may result in cirrhosis. In cirrhosis, the formation of fibrotic scar tissue leads to the progressive deterioration of liver function and other complications, including liver cancer (primarily hepatocellular carcinoma [HCC]) (37). The most common causes of cirrhosis in developed countries are alcohol abuse and chronic infections with hepatitis B and C viruses. Often associated with metabolic disorders, nonalcoholic fatty liver disease (NAFLD) is a liver condition that can progress to nonalcoholic steatohepatitis (NASH) in about one-third of NAFLD patients, thereby increasing the risk of cirrhosis and HCC (38).

A cross-sectional study in 177 subjects with chronic liver disease (especially chronic hepatitis B or C and NASH) found an association between daily caffeine intake >308 mg — equivalent to >2 cups/day of coffee — and a lower risk of having advanced liver fibrosis (39). Of note, no association was reported with non-coffee sources of caffeine like caffeinated soda or green and black tea (39). Recent cross-sectional studies also suggested a protective association of coffee intake against fibrosis development in patients with hepatitis C (40, 41). Additional studies have suggested that consumption of coffee, but not of caffeine, was inversely associated with the risk of advanced liver fibrosis in patients with NAFLD or NASH (42-44).

A recent meta-analysis of four case-control and three prospective cohort studies reported an inverse association between coffee consumption and risk of cirrhosis (45). In addition, a few large prospective cohort studies found that coffee drinking was associated with reduced mortality from alcoholic cirrhosis (46-49). A 17-year study of more than 51,000 men and women in Norway found that those who consumed ≥2 cups/day of coffee had a risk of cirrhosis-related death that was 40% lower than those who never consumed coffee (49). A 22-year prospective cohort study in 125,580 US adults found that coffee drinking was protective against alcoholic cirrhosis but not nonalcoholic cirrhosis (48). Specifically, the risk of developing alcoholic cirrhosis was 40% lower in those who drank 1 to 3 cups/day of coffee and 80% lower in those who drank ≥4 cups/day (48). Recent data from 63,275 Chinese participants of the Singapore Chinese Health Study showed that consumption of ≥2 cups/day of coffee was associated with a 66% lower risk of death from non-viral hepatitis-related cirrhosis — no such association was found with mortality from cirrhosis due to viral hepatitis (46).

Several case-control and prospective cohort studies have found significant inverse associations between coffee consumption and the risk of HCC (reviewed in 50). In a recent 18-year prospective cohort study of 162,022 US adults — comprising Japanese Americans, Caucasians, Mexican Americans, African Americans, and Native Hawaiians — consumption of coffee, but not decaffeinated coffee, was inversely associated with risk of developing HCC (51). Specifically, drinking 2 to 3 cups/day of coffee was associated with a 38% reduced risk of HCC compared to no coffee drinking (51). In addition, the risk of chronic liver disease-related mortality was 71% lower in individuals consuming ≥4 cups/day of regular coffee and 46% lower in those consuming ≥2 cups/day of decaffeinated coffee compared to non-consumers (51). A pooled analysis of this study with 10 other prospective cohort studies found an overall 46% lower risk of liver cancer with coffee consumption (see also Cancer) (52).

Cancer

Numerous observational studies have examined the relationship between coffee consumption and cancer risk (53, 54). Results from recently published meta-analyses of observational studies are reported in **Table 1**. In addition, a recent meta-analysis of prospective cohort studies by Wang et al. (54) investigated the relationships between the highest versus lowest categories of coffee intake and the risk of most cancer types. Coffee consumption was found to be associated with reduced risks of oral/pharyngeal cancer (6 studies; -31%), colon cancer (10 studies; -13%), liver cancer (9 studies; -54%), prostate cancer (14 studies; -11%), endometrial cancer (12 studies; -27%), and melanoma (6 studies; -11%) (54). Overall, these results are in agreement with those from other pooled analyses of prospective studies presented in **Table 1**. However, unlike the results reported by Wang et al. (54), coffee consumption has been inversely associated with the risk of colon cancer in case-control studies, but not in prospective cohort studies (see **Table 1**). Also, in the case of prostate cancer, several meta-analyses suggested a reduced risk with increased coffee intake in prospective but not case-control studies (54-56). However, whether this association exists only in certain study populations or at specific cancer stages remains unclear (57, 58). There seems to be little evidence of associations between coffee consumption and breast cancer, esophageal cancer, glioma, laryngeal cancer, pancreatic cancer, rectal cancer, stomach cancer, and thyroid cancer (**Table 1**) (54).

Table 1. Coffee and Cancer Risk: Meta-Analyses of Observational Studies

Type of Cancer	Type of Observational Studies	Relative Risk [RR] or Odds Ratio [OR]# (95% Confidence Interval)	Relative Risk [RR] or Odds Ratio [OR] in Subgroup Analyses (e.g., by study types)	References
Breast cancer	10 case-control and 16 prospective cohort studies	RR: 0.96 (0.93-1.00)	RR: 0.93 (0.86-1.00) for case-control studies RR: 0.98 (0.93-1.02) for cohort studies RR: 0.81 (0.67-0.97) for ER-negative cancer RR: 1.01 (0.93-1.09) for ER-positive cancer	Li et al. (2013; 59)
	20 case-control and 17 prospective cohort studies	RR: 0.97 (0.93-1.00)	RR: 0.94 (0.89-1.00) for case-control studies RR: 0.98 (0.95-1.02) for cohort studies RR: 0.99 (0.94-1.04) for caffeine RR: 0.98 (0.92-1.05) for decaffeinated coffee RR: 0.69 (0.53-0.89) among BRCA1 mutation carriers	Jiang et al. (2013; 60)
Colorectal cancer	25 case-control studies	OR: 0.85 (0.75-0.97)	OR: 0.68 (0.57-0.81) for colon cancer OR: 0.95 (0.79-1.15) for rectal cancer	Li et al. (2013; 61)
	16 prospective cohort studies	RR: 0.94 (0.88-1.01)	RR: 0.93 (0.86-1.01) for colon cancer RR: 0.98 (0.88-1.09) for rectal cancer	Li et al. (2013; 61)
	7 case-control and 5 prospective cohort studies	-	RR: 0.78 (0.65-0.95) for case-control studies RR: 0.82 (0.65-1.02) for cohort studies	Akter et al. (2016; 62)
	19 prospective cohort studies	RR: 0.98 (0.90-1.06)	RR: 0.92 (0.83-1.02) for colon cancer RR: 1.06 (0.95-1.19) for rectal cancer	Gan et al. (2017; 63)

Thyroid cancer	5 case-control and 2 prospective cohort studies	OR: 0.88 (0.71-1.07)		Han et al. (2017; 79)

#Odds ratio or relative risk of cancer for the highest vs. lowest categories of coffee intake.

Finally, there is some evidence suggesting a potential increase in the risk of lung cancer with the highest versus lowest levels of coffee intakes. Yet, cigarette smoking has a major confounding effect on this association (see Health risks associated with coffee consumption) (54, 70).

Mortality

Three large US prospective cohort studies, namely NHS I (74,890 women), NHS II (93,054 women), and HPFS (40,557 men), examined whether coffee drinking was associated with all-cause, cardiovascular disease-related, or cancer-related mortality (80). Compared to no coffee consumption, the consumption of coffee, whether caffeinated or decaffeinated, up to 5 cups/day, was inversely associated with all-cause mortality. There was no difference in risk of death between non-consumers and consumers of >5 cups/day of coffee. Coffee consumption was also found to be inversely associated with mortality related to cardiovascular disease, neurological disease, and suicide (80). Other large cohort studies have reported habitual consumption of any coffee being inversely associated with all-cause and cardiovascular disease-related mortality, but generally not with cancer-related mortality (81-86). Moreover, the associations have not always been consistent among women and men, especially regarding cancer-related mortality (85, 86). A dose-response meta-analysis of 21 prospective studies found a nonlinear inverse association between coffee consumption and all-cause and cardiovascular disease-related mortality (87). Consumption of only 1 cup/day of coffee was significantly associated with lower risk of all-cause (-8%) and cardiovascular disease-related mortality (-11%). The largest risk reductions for all-cause (-16%) and cardiovascular disease-related mortality (-21%) were found to be associated with the consumption of 4 cups/day and 3 cups/day of coffee, respectively (87).

Safety

Adverse effects

Most adverse effects attributed to coffee consumption are related to caffeine. In healthy adults, daily caffeine consumption ≤400 mg — corresponding to 6.5 mg/kg body weight/day for a 70-kg person — is usually not associated with adverse effects (88). Caffeine intakes of less than 300 mg/day in women of childbearing age (equivalent to 4.3 mg/kg body weight/day for a 70-kg woman) and less than 2.5 mg/kg body weight/day in children are unlikely to cause adverse effects (88).

Adverse reactions to caffeine may include tachycardia (rapid heart rate), palpitations, insomnia, restlessness, nervousness, tremor, headache, abdominal pain, nausea, vomiting, diarrhea, and diuresis (increased urination) (89). Very high caffeine intakes, not usually from coffee, may induce hypokalemia (abnormally low serum potassium) (90). Sudden cessation of caffeine consumption after long-term use may result in caffeine withdrawal symptoms (91). Gradual withdrawal from caffeine appears less likely to result in withdrawal symptoms than abrupt withdrawal (92). Commonly reported caffeine withdrawal symptoms include headache, fatigue, drowsiness, irritability, difficulty concentrating, and depressed mood.

Potential health risks associated with regular coffee consumption

Cardiovascular disease

Serum lipids: An early meta-analysis of nine randomized controlled trials found that the consumption of unfiltered, boiled coffee dose-dependently increased serum total and LDL-cholesterol concentrations, while the consumption of filtered coffee resulted in very little change (93). A more recent meta-analysis of 12 randomized controlled trials reported that the consumption of coffee increased serum total cholesterol by 8.1 mg/dL, LDL-cholesterol by 5.1 mg/dL, and triglycerides by 12.6 mg/dL (94). The consumption of filtered coffee raised total cholesterol by only 3.6 mg/dL compared to an increase of 12.9 mg/dL with unfiltered coffee consumption. Unlike filtered coffee, consumption of unfiltered coffee significantly increased LDL-cholesterol and triglycerides by 11.9 mg/dL and 18.8 mg/dL, respectively (94). The cholesterol-raising factors in unfiltered coffee have been identified as cafestol and kahweol, two diterpenes that are largely removed from coffee by paper filters (see Diterpenes) (10).

Homocysteine: An elevated plasma total homocysteine concentration has been associated with increased risk of cardiovascular disease, including coronary heart disease, stroke, and peripheral vascular disease, but the relationship may not be causal (95). Higher coffee intakes have been associated with increased plasma homocysteine concentrations in cross-sectional studies conducted in Europe, Scandinavia, and the US (96-100). Controlled clinical trials have confirmed the homocysteine-raising effect of coffee at intakes of about 4 cups/day (101-103).

Hypertension: Hypertension is a well-recognized risk factor for cardiovascular disease. Two meta-analyses of randomized controlled trials showed that high intakes of coffee (3 to 5 cups/day) for <85 days significantly increased systolic/diastolic blood pressure by 1.2/0.5 mm Hg (104) or 2.4/1.2 mm Hg (105). Although the increases in blood pressure seem modest by individual standards, it has been estimated that an average systolic blood pressure reduction of 2 mm Hg in a population may result in 10% lower mortality from stroke and 7% lower mortality from coronary heart disease (106). However, a more recent pooled analysis excluding the trials that used decaffeinated coffee in control groups — and thus assessed the effect of caffeine rather than that of coffee — found no significant changes in systolic blood pressure and diastolic blood pressure with high coffee intakes (107). Additionally, two meta-analyses combined the data from observational studies that examined prospectively the association between habitual coffee consumption and risk of hypertension (107, 108). One meta-analysis of six prospective cohort studies included 172,567 non-hypertensive participants (one study enrolled pre-hypertensive subjects) of which 37,135 cases of incident hypertension were reported over follow-up periods spanning from 6.4 years to 33 years (108). Compared to coffee intakes of <1 cup/day, intakes of 1 to 3 cups/day were found to be associated with a 9% increased risk of hypertension. However, no such association could be observed for coffee intakes >3 cups/day (108). Another meta-analysis of four prospective cohort studies found no association between coffee consumption and risk of hypertension (107). Also, a recent analysis of data from 29,985 postmenopausal women followed for nearly four years in the Women's Health Initiative Observational Study found no increased risk of hypertension with intakes of caffeinated coffee, decaffeinated coffee, or caffeine (109).

While there is little evidence of an association between long-term coffee consumption and risk of hypertension, the available evidence from trials suggests that consumption of caffeine modestly raises systolic blood pressure. Whether this may result in increased risk of stroke and coronary heart disease in the population, particularly in those with hypertension, is still uncertain. Yet, to date, regular coffee consumption in hypertensive subjects has not been associated with an increased risk of cardiovascular disease (110).

Coronary heart disease: A meta-analysis of 20 prospective cohort studies, including 407,806 participants and 15,599 incident coronary heart disease (CHD) cases, found no significant association between coffee consumption and CHD risk (111). Yet, a more recent meta-analysis of 22 prospective cohort studies reported a modest reduction in CHD risk with moderate (3-5 cups/day) — but not high (≥6 cups/day) — coffee intakes compared to low intakes (<1 cup/day) (112).

In addition, cross-sectional studies have provided little evidence that the formation of atherosclerotic plaques, an early event in the development of CHD, is more prevalent in regular coffee drinkers than in non-drinkers (113-116). Coffee consumption has not been linked to the development of atherosclerosis in two prospective cohort studies. In the Coronary Artery Risk Development in Young Adults (CARDIA) study that followed approximately 4,000 young US adults for 15 to 20 years, there was no evidence of an association between regular coffee intake and progression of coronary artery calcification, a measure of subclinical atherosclerosis (117). Moreover, in the Multi-Ethnic Study of Atherosclerosis (MESA) that followed about 6,500 US adults over a median period of 11.1 years, occasional but not regular drinking of coffee was associated with a 28% increased risk of cardiovascular disease compared with no drinking (114). This study found no association between coffee intake and progression of coronary artery calcification (114).

Cardiac arrhythmias: Early clinical trials found coffee or caffeine intake equivalent to 5 to 6 cups/day did not increas the frequency or severity of cardiac arrhythmias in healthy people or in people with coronary heart disease (118, 119). A meta-analysis of six prospective cohort studies in 214,316 participants found no association between coffee consumption and risk of atrial fibrillation, the most common type of cardiac arrhythmias. In addition, a recent meta-analysis of 11 short-term intervention studies (single dose to two-week trials) found that caffeine consumption did not increase the occurrence of ventricular arrhythmias (120). Finally, two meta-analyses of observational studies found no evidence to suggest that caffeine consumption was associated with an increased risk of atrial fibrillation and even reported a modest reduction in risk with moderate intakes (121, 122).

Thus, consumption of coffee or caffeine at usual intakes does not appear to increase the risk of cardiac arrhythmias. The current evidence does not support clinical recommendations that discourage moderate consumption of coffee in patients at risk or with suspicions of cardiac arrhythmia (120, 123).

Stroke: A 2011 meta-analysis that included eight prospective cohort studies — all following participants who were free of cardiovascular disease and diabetes mellitus at baseline — found that consumption of 3 to 4 cups/day of coffee was associated with an 18% lower risk of stroke compared with no consumption and that higher intakes were not associated with an increased risk (124). Since this meta-analysis, a few large prospective studies have reported mixed results on the association between coffee consumption and stroke incidence or stroke-related mortality. Results from 42,659 participants in the German cohort of the European Prospective Investigation in Cancer and Nutrition (EPIC-Germany) reported no association between coffee consumption and stroke incidence over an 8.9 year-period (125). Compared to no intake, consumption of ≥3-6 cups/week of coffee was associated with a reduced risk of stroke in a prospective study of 82,369 Japanese participants (126). Also, the consumption of 4 to 5 cups/day of coffee was associated with a reduced risk of stroke-related mortality among men, but not women, followed in the large prospective NIH-AARP Diet and Health Study (81).

Lung cancer

Several observational studies have examined the relationship between coffee intake and lung cancer risk in humans. A recent meta-analysis of 12 case-control and 5 prospective cohort studies, including a total of 12,276 cases and 102,516 controls, found an overall 31% increased risk of lung cancer with the highest versus lowest levels of coffee intake (see **Table 1**). Subgroup analyses outlined a significant increase in lung cancer risk with coffee intake in hospital-based case-control (+36%) and prospective cohort studies (+59%), in studies conducted in American (+34%) and Asian (+49%) populations, in men (+41%), and in smokers (+24%); conversely, no significant association between coffee intake and lung cancer risk was found in community-based case-control studies, in studies conducted in European populations, in women, and in non-smokers (70). Another meta-analysis of 13 case-control and 8 prospective cohort studies, including 19,892 cases and 623,645 controls, found a 9% increased risk of lung cancer in coffee drinkers compared to non-drinkers (127). However, a pooled analysis restricted to the 16 (out of 21) studies that adjusted for smoking found no significant association between coffee intake and risk of lung cancer [RR: 1.03 (0.95-1.12)].

Cigarette smoking is a major confounding factor in the association between coffee consumption and lung cancer risk, and the evidence suggests that coffee intake is unlikely to be a risk factor for lung cancer. Of note, residual confounding by smoking remains a concern when a slight increase in lung cancer risk is still observed in studies even after adjustment for tobacco smoking (127).

Adverse pregnancy outcomes

It has been suggested that *in utero* exposure to caffeine through maternal coffee consumption might have adverse effects on the embryo/fetus during pregnancy and the offspring.

Miscarriage: The results of observational studies that have examined the relationship between maternal coffee or caffeine intake and the risk of miscarriage (spontaneous abortion) have been conflicting. While some prospective cohort studies have observed significant associations between high caffeine intakes, particularly from coffee, and the risk of spontaneous abortion (128-132), other studies have not (133-136). The most recent meta-analysis of 14 prospective cohort studies in 130,456 pregnant women and 3,429 cases of miscarriage found risk of miscarriage increased by 40% and 72% with maternal caffeine intakes of 350 to 699 mg/day and ≥700 mg/day during pregnancy, respectively (137). No significant associations were found for daily doses of caffeine less than 350 mg. A dose-response analysis found a 7% increase in the risk of miscarriage per 100 mg/day-increment in caffeine intake during pregnancy (137). Of note, one prospective cohort study that assessed caffeine intake by measuring serum concentrations of paraxanthine, a caffeine metabolite, found that the risk of spontaneous abortion was only elevated in women with paraxanthine concentrations that suggested caffeine intakes of ≥600 mg/day (138).

It has been proposed that an association between caffeine consumption and the risk of spontaneous abortion could be explained by the relationship between nausea and fetal viability (139). Nausea is more common in women with viable pregnancies than nonviable pregnancies, such that women with viable pregnancies may be more likely avoid or limit caffeine consumption due to nausea (140). However, at least one study found that the significant increase in risk of spontaneous abortion observed in women with caffeine intakes >300 mg/day was independent of nausea in pregnancy (141). Additionally, two other studies found that caffeine consumption was associated with an increased risk of spontaneous abortion in women who experienced nausea or aversion to coffee during pregnancy (131, 142). Nonetheless, this does not exclude the possibility of reverse causality, when the loss of fetal viability results in reduction of pregnancy symptoms, like nausea and aversion to coffee, and may be followed by an increase in coffee intake (137).

Of note, consumption of <400 mg/day of caffeine or <4 cups/day of caffeinated coffee by women prior to pregnancy has not been linked to the risk of miscarriage in an analysis of a large prospective study (NHS I) that followed 11,072 women and a total of 15,590 pregnancies (143).

Although the topic remains unsettled, the American College of Obstetricians and Gynecologists recommends that women limit their daily caffeine intake to <200 mg during pregnancy (144).

Intrauterine growth restriction and low birth weight: Observational studies examining the effects of maternal caffeine and coffee consumption on fetal growth have assessed intrauterine growth restriction (IUGR; also known as small-for-gestational age; defined as fetal weight <10th percentile for gestational age), and/or incidence of low birth weight (defined as weight at birth <2,500 g [5.5 pounds]).

A recent meta-analysis of eight prospective cohort and four case-control studies reported a 38% increased risk of low birth weight with the highest versus lowest intakes of caffeine during pregnancy (145). This risk appeared to increase linearly with incremental doses of caffeine (145, 146). A dose-response meta-analysis of six prospective cohort and five case-control studies found a 7% increased risk of low-birth-weight infants per 100 mg of caffeine consumed daily during pregnancy (146). Likewise, a 100 mg-increment in maternal caffeine intakes has been associated with a 10% increased risk of small-for-gestational age infants in the dose-response analysis of 10 prospective cohort and 5 case-control studies (146).

At present, only one study has examined the impact of limiting caffeine intake during pregnancy on birth weight. In a double-blind, intervention trial that randomized 1,197 regular coffee drinkers (≥3 cups/day of coffee) to drink decaffeinated (median caffeine intake of 117 mg/day) or caffeinated coffee (median caffeine intake of 317 mg/day) throughout the second half of their pregnancy, no differences in length of gestation or infant birth weight were found between the two groups (147).

Although the relationship between maternal caffeine consumption and fetal growth requires further clarification, it appears that even moderate caffeine intakes might adversely affect fetal growth in non-smoking women (145, 146, 148). Limiting caffeine intake to ≤100 mg/day (≤1 cup/day of coffee) during pregnancy may be recommended to avoid any adverse effect, assuming that the associations of caffeine intake with the risk of IUGR and low birth weight are causal (145, 146).

Birth defects: Potential relationships between coffee consumption during pregnancy and congenital birth defects have been investigated in the US population-based National Birth Defects Prevention Study (NBDPS), an ongoing multi-site case-control study. In an analysis that included mothers of 1,531 infants with cleft lips (with or without cleft palates), 813 infants with cleft palates only, and 5,711 control infants, no association was found between the highest versus lowest intakes of coffee and caffeine and the risk of orofacial clefts (149). Another analysis, including mothers of 3,346 cases and 6,642 control infants, suggested an increased risk of anotia/microtia and craniosynostosis with the consumption of coffee or caffeine. However, no dose-response could be detected (150). Further, an analysis of the NBDPS in mothers of 844 infants with limb deficiencies and 8,069 control infants found no increased risk associated with coffee and/or caffeine intake during pregnancy (151). There was no association between maternal coffee or caffeine intake during pregnancy and risk of congenital talipes equinovarus (known as "clubfoot") in another US population-based case-control study of mothers of 646 infants with isolated clubfoot and 2,037 control infants (152). Finally, a recent meta-analysis that combined data from one prospective cohort study and six case-control studies found no association between maternal coffee consumption during pregnancy and risk of neural tube defects (153).

At present, there is no convincing evidence that maternal consumption of 3 cups/day of coffee or 300 mg/day of caffeine during pregnancy increases the risk of congenital malformations in humans.

Childhood acute leukemia: The etiology of acute lymphoblastic leukemia (ALL) and acute myeloblastic leukemia (AML), which primarily affect children, is unclear. It has been suggested that exposure to caffeine during pregnancy might have long-lasting adverse effects on the health of the offspring. A meta-analysis of seven case-control studies that examined maternal coffee consumption during pregnancy in relation to the incidence of childhood acute leukemia found coffee consumption was associated with increased risks of overall acute leukemia (+72%), ALL (+65%), and AML (+58%) (154). Another meta-analysis of eight case-control studies found an increased risk of ALL (+43%), but not AML, with the highest versus lowest intakes of coffee during pregnancy (155). High versus low consumption of other sources of caffeine during pregnancy (tea, cola beverages) and childhood (cola beverages) were not found to be associated with childhood acute leukemia (155).

The evidence of a positive association between maternal coffee intake and childhood acute leukemia is currently limited to case-control studies. Case-control studies usually include more cancer cases than prospective cohort studies, but they are subject to recall bias with respect to coffee consumption and selection bias with respect to the control group (156). Further studies with a prospective design are needed to confirm the possible link between coffee intake during pregnancy and childhood acute leukemia.

Lactation

The American Academy of Pediatrics categorizes caffeine as a maternal medication that is usually compatible with breast-feeding (157). Although high maternal caffeine intakes have been reported to cause irritability and poor sleeping patterns in infants, no adverse effects have been reported with moderate maternal intake of caffeinated beverages equivalent to 2 to 3 cups of coffee daily.

Nutrient interactions

Calcium, osteoporosis, and risk of fracture

Osteoporosis is a multifactorial bone disorder that compromises bone mass and strength and increases the risk of fracture. The results of early controlled studies in humans indicated that coffee and caffeine consumption decreased the efficiency of calcium absorption resulting in a loss of about 4 to 6 mg of calcium per cup of coffee (158, 159). However, there is little evidence to suggest detrimental effects of coffee on bone health in populations with adequate calcium intakes (160). To date, results from observational studies that examined associations between coffee intakes and measures of bone mineral density (BMD) loss — generally used to diagnose osteoporosis — have been mixed (161-164). Further, two meta-analyses of observational studies reported no significant associations between coffee intake and risk of hip fracture (165, 166). A third meta-analysis of six case-control and nine prospective cohort studies found no overall association between coffee intake and total fracture (167). Yet, a gender subgroup analysis of eight studies showed a 14% increased risk of fracture in women — but not in men — with the highest versus lowest intakes of coffee. Another subgroup analysis of six studies found a 35% increased risk of osteoporotic fracture in participants with the highest versus lowest intakes of coffee (167).

Current evidence is scarce to suggest that coffee consumption could increase the risk of bone loss and fracture. Limiting coffee consumption to ≤3 cups/day while ensuring adequate calcium and vitamin D intakes should prevent any potential adverse effects on calcium absorption and bone health.

Nonheme iron

Phenolic compounds in coffee can bind nonheme iron and inhibit its intestinal absorption (168). Drinking 150 to 250 mL of coffee with a test meal has been found to inhibit iron absorption by 24%-73% (169, 170). To maximize iron absorption from a meal or supplements, people with poor iron status should not consume coffee at the same time.

Drug interactions

Habitual caffeine consumption increases hepatic cytochrome P450 (CYP) 1A2 activity, which has implications for the metabolism for a number of medications (171). Conversely, drugs that inhibit the activity of CYP1A2 interfere with the metabolism and elimination of caffeine, thereby increasing the risk of adverse effects (172).

Drugs that alter caffeine metabolism

The following medications may impair the hepatic metabolism of caffeine, delaying its excretion and potentially increasing the risk of caffeine-related side effects: cimetidine (Tagamet), disulfiram (Antabuse), estrogens, fluconazole (Diflucan), fluvoxamine (Luvox), mexiletine (Mexitil), quinolone class antibiotics (Cipro, Avelox), riluzole (Rilutek), terbinafine (Lamisil), and Verapamil (Calan) (173). Concomitant use of ephedrine and caffeine can lead to life-threatening adverse effects, including heart attack, stroke, seizures, and death (173). Use of the drug phenytoin (Dilantin) or cigarette smoking increases the hepatic metabolism of caffeine, resulting in increased elimination and decreased plasma caffeine concentrations (89).

Caffeine effects on other drugs

Caffeine and other methylxanthines may enhance the effects and side effects of β-adrenergic stimulating agents, such as epinephrine and albuterol (89, 171). Caffeine doses of 400 to 1,000 mg may inhibit the hepatic metabolism of the antipsychotic medication, clozapine (Clozaril), potentially elevating serum clozapine concentration and increasing the risk of toxicity. Those taking levothyroxine are advised to avoid drinking coffee at the same time they take their medication because coffee may reduce the absorption of levothyroxine in some patients. Caffeine consumption can decrease the elimination of theophylline, potentially increasing serum theophylline levels. Caffeine has been also found to decrease the systemic elimination of acetaminophen (i.e., paracetamol) and to increase the bioavailability of aspirin, which may partially explain its efficacy in enhancing their analgesic effects. This is important because many pain-relievers on the market today combine caffeine with aspirin and/or acetaminophen. Further, caffeine may decrease the bioavailability of lithium and alendronate (Fosamax) by enhancing their elimination (173).

Summary

- Tea is an infusion of the leaves of the *Camellia sinensis* plant, which is not to be confused with herbal teas. *(More information)*
- All the tea types, including white, green, oolong, black, and Pu-erh tea, are produced from the leaves of the *Camellia sinensis* plant. Different processing methods yield the various types of tea. *(More information)*
- Biologically active chemicals in tea include flavonoids, caffeine, fluoride, and theanine. Green teas are especially rich in a group of flavonoids called flavan-3-ol monomers or catechins. Black teas contain more complex chemicals — theaflavins and thearubigins — derived from catechins. *(More information)*
- Observational studies in humans suggest that daily consumption of tea may be associated with a reduced risk of cardiovascular disease (CVD). Intervention studies showed that tea exhibited cholesterol-lowering, anti-inflammatory, antioxidant, and anti-hypertensive properties, which might be beneficial in the prevention of CVD. *(More information)*
- Tea consumption has been associated with reduced risk of developing type 2 diabetes mellitus in large prospective cohort studies. Yet, the mechanisms behind this association are complex, possibly involving a role for tea bioactive compounds in the regulation of energy balance, lipid and glucose metabolism, insulin sensitivity, body composition, and/or body temperature. *(More information)*
- Despite promising results from animal studies, current evidence does not support a role for tea consumption in the prevention of most cancers in humans. *(More information)*
- It is still unclear whether tea consumption is associated with increased bone mineral density and/or reduced risk of osteoporotic fractures. *(More information)*
- Limited research suggests an inverse association between tea consumption and risk of tooth cavities. The incorporation of green tea extract in mouthwashes and/or toothpastes may also help reduce dental plaque and gum inflammation in patients. *(More information)*
- The pooled analysis of three large US prospective cohort studies found an 11% lower risk of kidney stones with the highest versus lowest level of tea intake. More research is needed to assess whether the oxalate content in tea may affect subjects with a history of kidney stones. *(More information)*
- The mounting evidence for a role of tea consumption in the prevention of cognitive decline comes from observational studies. Clinical studies would be needed to establish whether tea or its bioactive constituents could limit cognitive decline and/or improve cognitive dysfunction in older individuals. *(More information)*
- The use of green tea extracts in clinical trials was found to cause gastrointestinal disorders and liver toxicity. Tea consumption may also potentially interfere with certain medications, including the anticoagulant, warfarin, and some cardiovascular drugs. *(More information)*

Introduction

Tea is an infusion of the leaves of the *Camellia sinensis* plant and, aside from water, is the most widely consumed beverage in the world (1). Different processing methods of tea leaves involve variable degrees of oxidation yielding different types of tea (green, oolong, or black tea). In 2014, Americans consumed 3.6 billion gallons of tea, of which 84% was black tea, 15% was green tea, and the remaining was white, oolong, and dark tea (2). Herbal teas are infusions of herbs or plants other than *Camellia sinensis* and will not be discussed in this article. Although tea contains a number of bioactive chemicals, including caffeine and fluoride, most research has focused on the potential health benefits of a class of compounds in tea known as flavonoids. In many cultures, tea is an important source of dietary flavonoids.

Definitions

Types of tea

All teas are derived from the leaves of the tea plant *Camellia sinensis*, but different processing methods produce different types of tea. Fresh tea leaves are rich in polyphenolic compounds known as flavonoids (see the article on Flavonoids). Flavonoids are divided in six subclasses: flavan-3-ols, anthocyanidins, flavanones, flavonols, flavones, and isoflavones (**Figure 1**). Tea leaves contain a polyphenol oxidase (PPO) enzyme in separate compartments from flavan-3-ol monomers or catechins (**Figure 2**) (3). When tea leaves are intentionally broken or rolled during processing, cell compartmentalization is disrupted and PPO comes into contact with catechins. This causes catechins to condense (join together) forming dimers and polymers known as theaflavins (**Figure 3**) and thearubigins, respectively (4). This oxidation process is often described as "fermentation" in the tea industry. Steaming, firing, or baking tea leaves inactivates PPO and stops the oxidation process (5).

The two prominent varieties of *Camellia sinensis* used in tea cultivation are *Camellia sinensis var. sinensis* and *Camellia sinensis var. assamica*. The former is native of China and usually used to make white and green tea. The latter originates from the Assam region of India, as well as regions of Southeast Asia, and is often used to make black teas, including pu-erh tea in the Yunnan province of China.

Although there are thousands of tea cultivars derived from the principal *Camellia sinensis* tea varieties, teas are usually divided into five types based on the extent of oxidation they undergo during processing. The withering method (the process of allowing the fresh leaves to dry) and the process of deactivating PPO may also differ among tea preparations (1).

Figure 1. Basic Structures of Flavonoid Subclasses

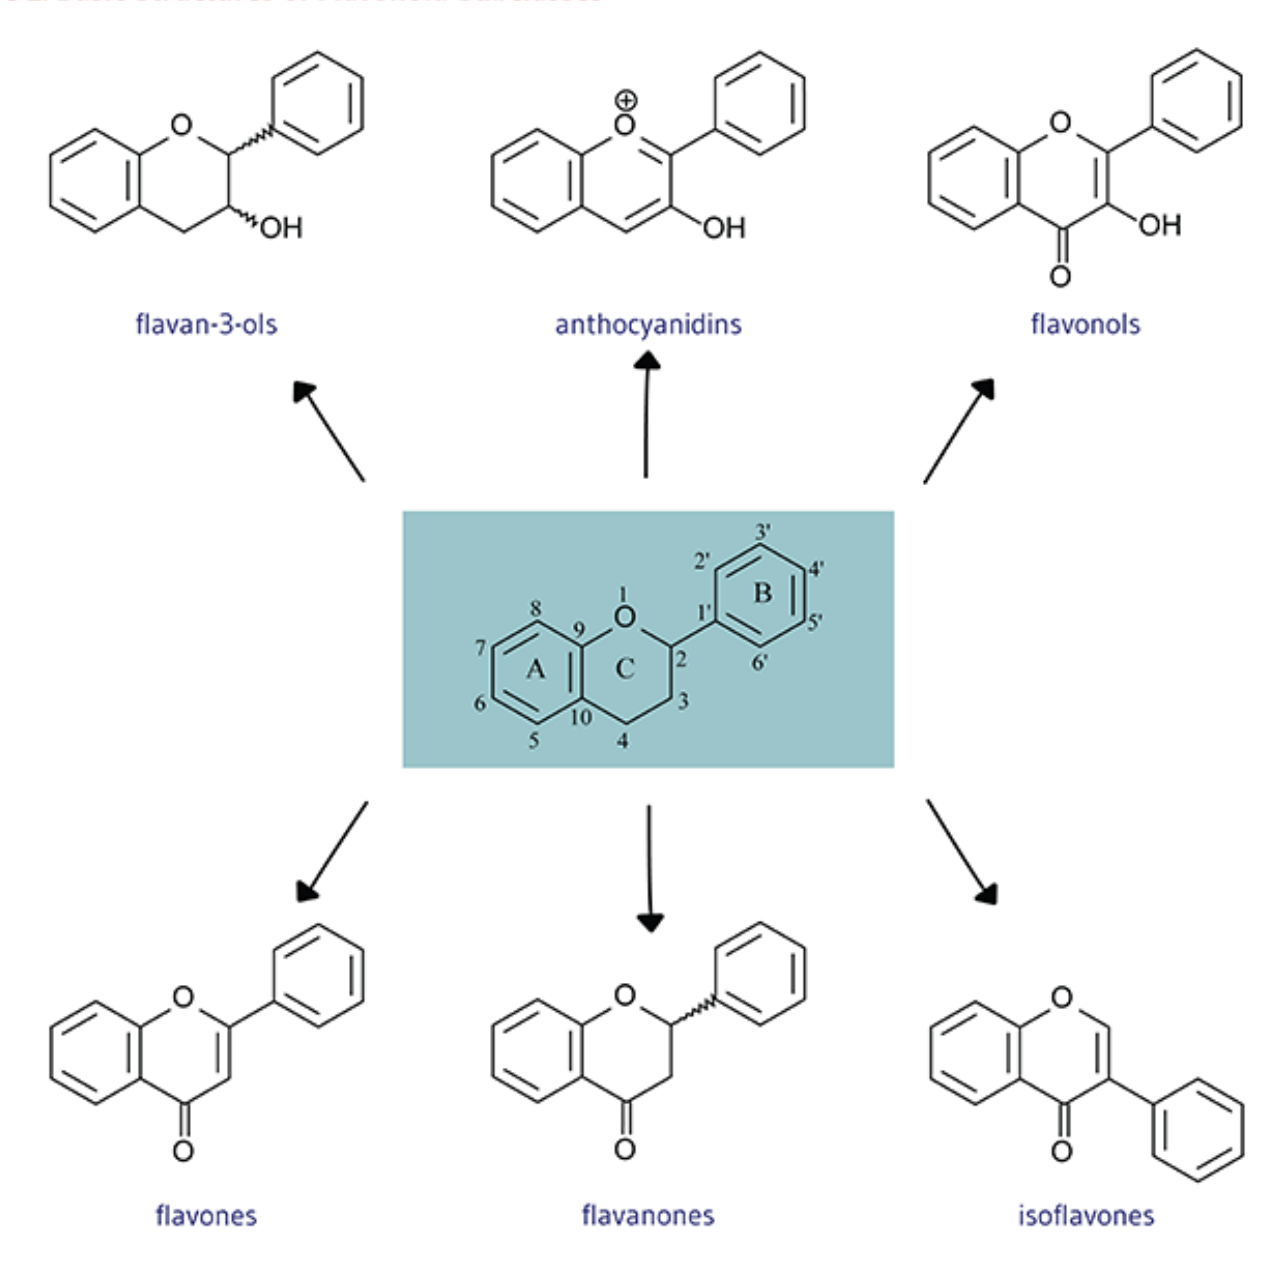

Figure 2. Chemical Structures of Principal Flavan-3-ols (Catechins) in Tea

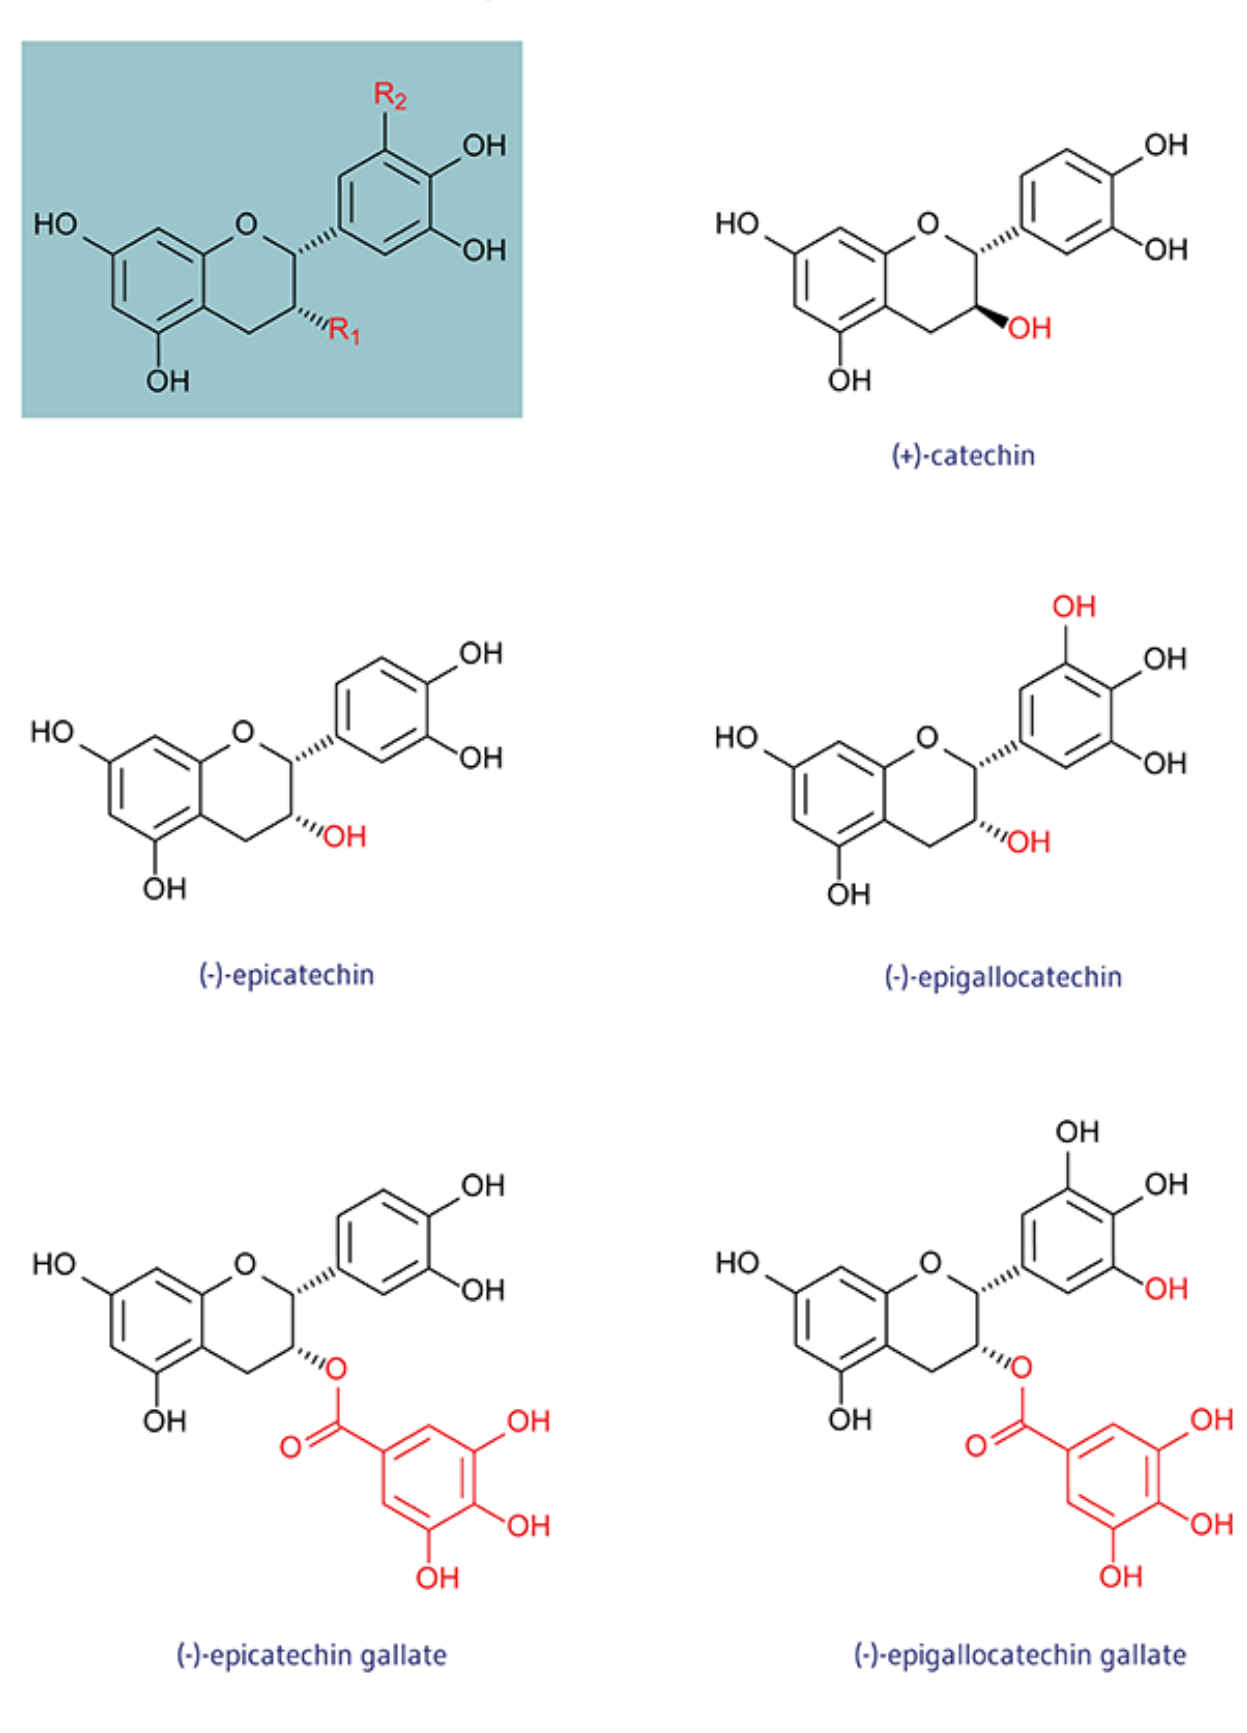

Figure 3. Chemical Structures of Some Theaflavins in Tea

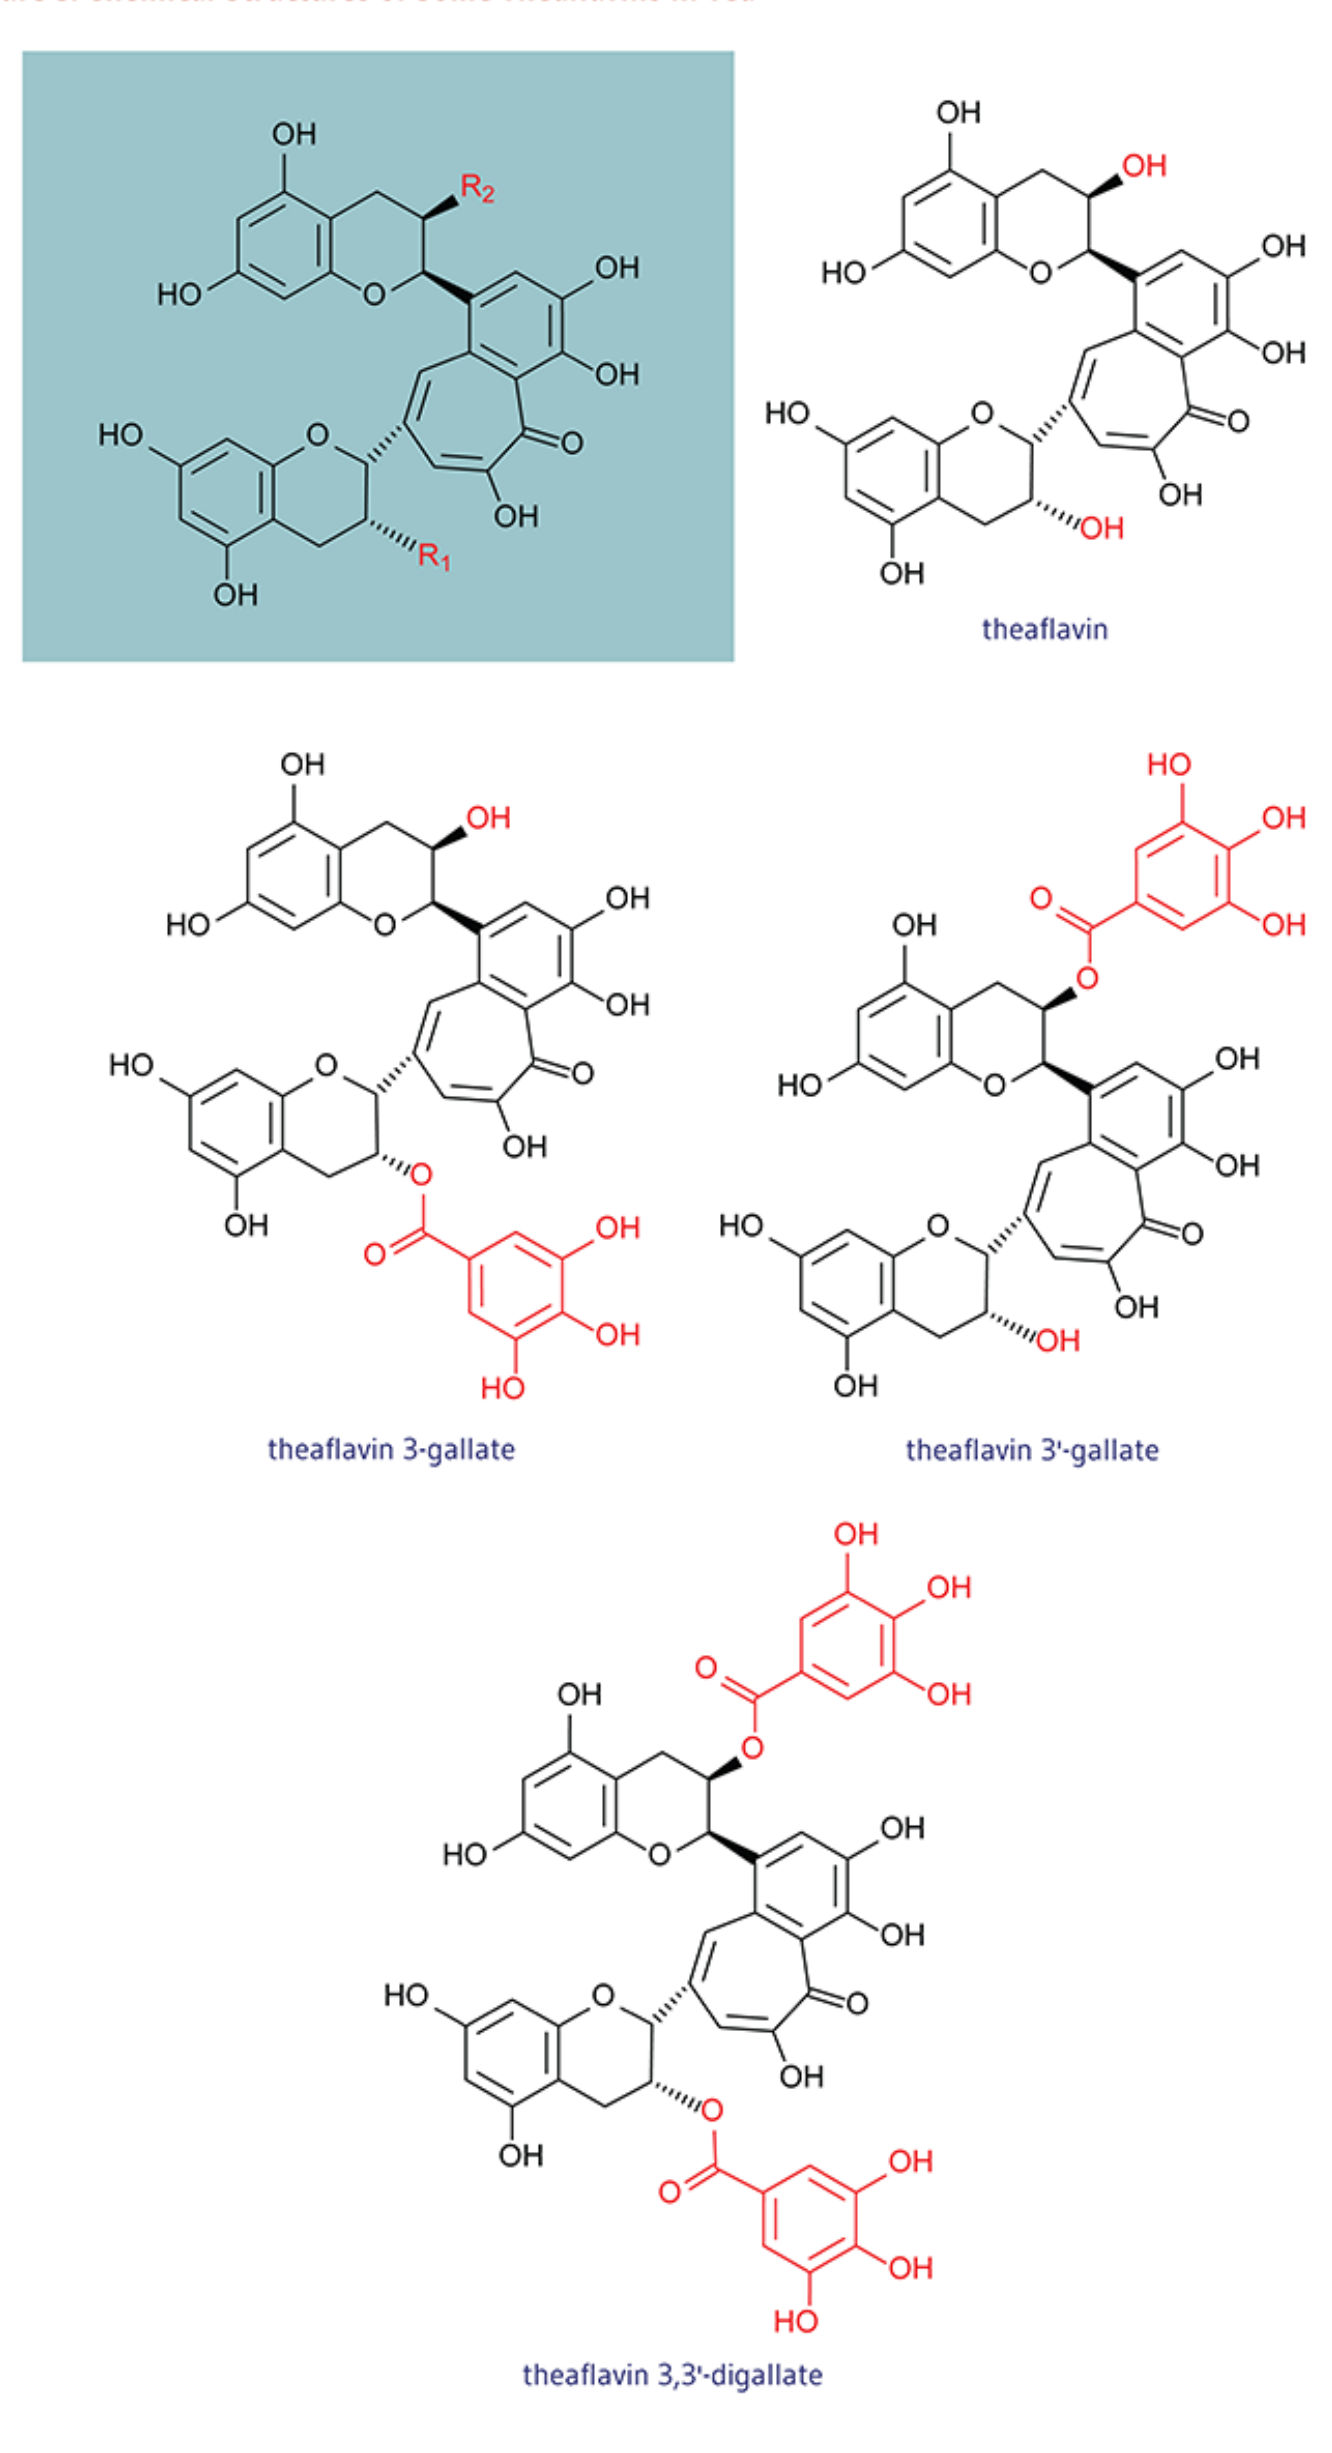


White tea

White tea is made from unopened buds and immature leaves, which are steamed or fired to inactivate polyphenol oxidase, and then dried. Thus, due to minimal oxidation, white tea retains the high concentrations of catechins present in fresh tea leaves (see Flavonoids below).

Green tea

Green tea is made from more mature tea leaves than white tea, and tea leaves may be withered prior to steaming or firing, and then rolled and dried. Like white teas, green teas are high in catechins, but the total content and composition of catechins may vary depending on the cultivar and the commercial source (6). Of note, green teas and white teas may sometimes contain similar amounts of catechins but still exhibit different antioxidant capacities; this is due to the presence of other non-catechin antioxidants in teas (6).

Oolong (Wulong) tea

Tea leaves destined to become oolong teas are "bruised" to allow the release of some of the polyphenol oxidase present in the leaves. Oolong teas are allowed to oxidize to a greater extent than for white or green teas, but for less time than black teas, before they are heated and dried. Consequently, the catechin, theaflavin, and thearubigin levels in oolong teas are generally between those of unfermented green and white teas and completely oxidized black teas (1).

Black tea

Tea leaves destined to become black tea are fully rolled or broken to maximize the interaction between catechins and polyphenol oxidase. Because they are allowed to oxidize completely before drying, most black teas are relatively low in monomeric flavan-3-ols, like (-)-epigallocatechin gallate (EGCG), and rich in theaflavins (2%-6% of extracted solids) and thearubigins (>20% of extracted solids) (see **Table 1** below). Some theaflavins have shown greater antioxidant activities than EGCG (7).

Pu-erh tea (also pu'erh tea, pu'er tea, or Chinese black tea)

Most pu-erh tea is produced in the Yunnan province of China from the larger leaves of the *assamica* variety of *Camellia sinensis*. The making process may include both enzymatic oxidation and fungus-led fermentation. In the case of "raw (aged) pu-erh tea," the initial preparation resembles that used to make green tea. The leaves are heated, dried, and then dampened before being pan-fired and compressed; the preparation is then carefully stored in a controlled environment and left to age for decades. A faster aging process, combining oxidation and fermentation by the fungus *Aspergillus niger* for several months, can also be used to produce "ripened pu-erh tea."

Cup sizes

The definition of a cup of tea varies in different countries or regions. In Japan, a typical cup of green tea may contain only 100 mL (3.5 ounces). A traditional European teacup holds approximately 125 to 150 mL (5 ounces), while a mug of tea may contain about 240 mL (8 ounces).

Bioactive Compounds in Tea

Tea contains over 2,000 components, including polyphenols (flavonoids), pigments (carotenoids and chlorophyll), alkaloids (caffeine, theophylline, theobromine), lignans, carbohydrates, lipids, proteins, amino acids (including L-theanine), vitamins (vitamin C, vitamin E, riboflavin), and various minerals and trace elements (8). Only some of them are described below.

Flavonoids

Dietary flavonoids are divided in six subclasses: flavan-3-ols, anthocyanidins, flavanones, flavonols, flavones, and isoflavones (see the article on Flavonoids). Total flavonoid content in green tea and black tea is of about 138 mg and 118 mg per 100 mL, respectively (9). A major subclass of flavonoids in tea is that of flavan-3-ols. Flavan-3-ol monomers, also known as catechins, constitute 30%-42% of the solid weight of brewed green tea. The principal catechins found in tea are (-)-epicatechin (EC), (-)-epigallocatechin (EGC), (-)-epicatechin gallate (ECG), and (-)-epigallocatechin gallate (EGCG) (see **Figure 2**). When catechins are enzymatically oxidized by polyphenol oxidase during the oxidation process that yields black tea, they form low molecular weight dimers known as theaflavins (see **Figure 3**) and complex polymers (of mostly unknown structures) called thearubigins. Non-oxidized teas are rich in catechins, while fully oxidized teas are rich in theaflavins and thearubigins (**Table 1**) (5).

Table 1. Flavan-3-ol Monomers and Thearubigins Content of Tea (mg/100 mL) (10)

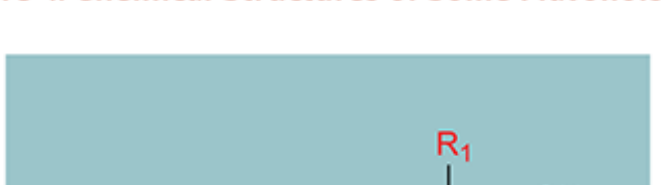
Type of Tea[1]	EC	ECG	EGC	EGCG	Thearubigins
Tea, white, brewed	-[2]	8.3	18.6	42.4	-
Tea, green, brewed	8.3	17.9	29.2	70.2	1.1
Tea, oolong, brewed	2.5	6.3	6.1	34.5	-
Tea, black, brewed	2.1	5.9	8.0	9.4	81.3

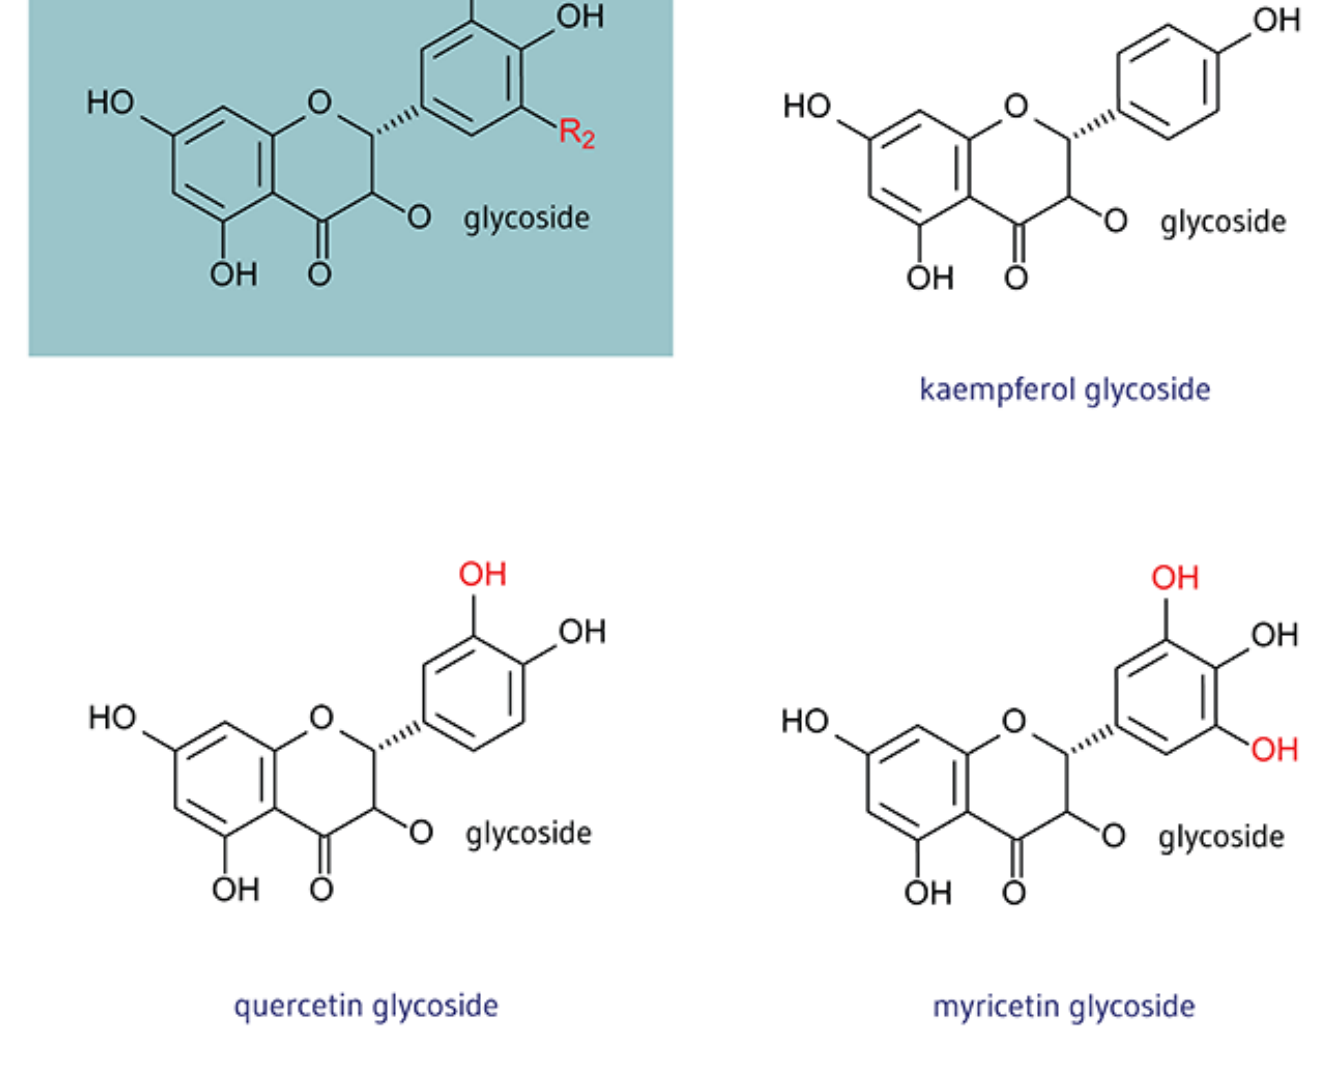
[1] 1 g of tea leaves infused in 100 mL of boiling water (1% weight/volume)

[2] The lack of a value for a particular flavonoid in a food in the database does not imply a zero value, but only that data were unavailable.

Tea is also a good source of another class of flavonoids called flavonols. Flavonols found in tea include kaempferol, quercetin, and myricetin. The flavonol content of tea is minimally affected by processing, and flavonols are present in comparable quantities in oxidized and non-oxidized teas. Unlike flavan-3-ols, flavonols are usually present in tea as glycosides, i.e., bound to a sugar molecule (**Figure 4**). Despite their poor bioavailability, flavonoids are thought to contribute substantially to the health benefits associated with daily tea consumption (10). For more detailed information, see the article on Flavonoids.

Figure 4. Chemical Structures of Some Flavonols in Tea





Caffeine

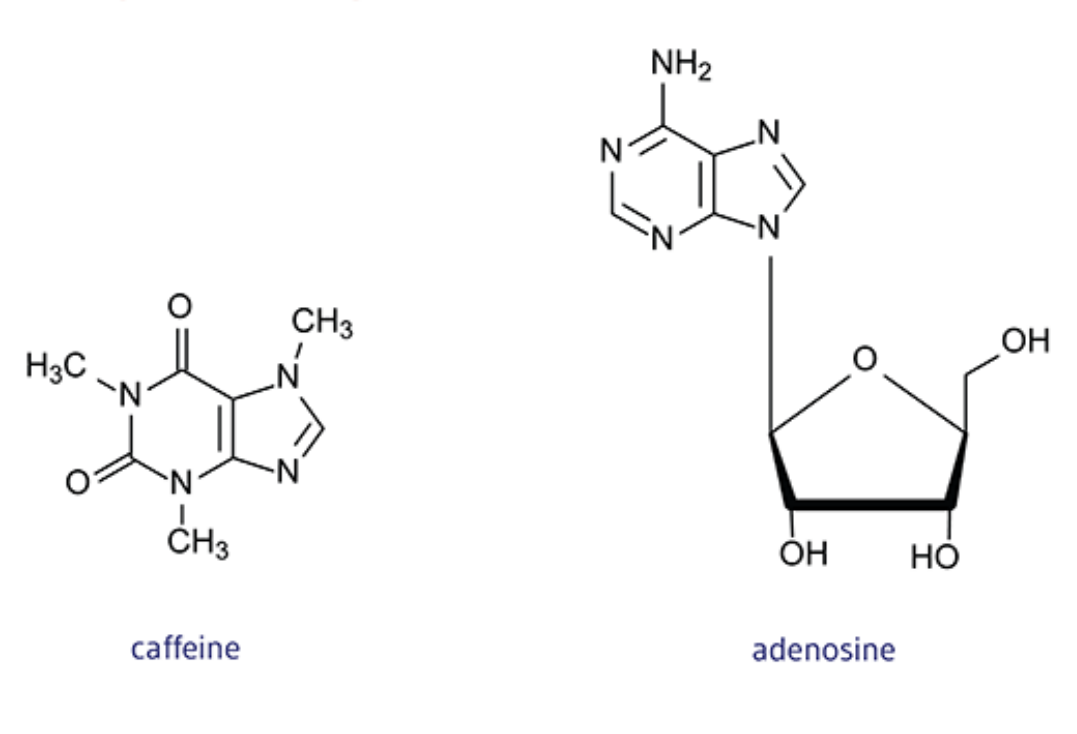
All teas contain caffeine, unless they are deliberately decaffeinated during processing. The caffeine content of different varieties of tea may vary considerably and is influenced by factors like brewing time, the amount of tea and water used for brewing, and whether the tea is loose or in teabags. In general, a mug of tea contains about half as much caffeine as a mug of coffee (11). The caffeine contents of more than 20 green and black teas prepared according to package directions are presented in **Table 2** (12). The caffeine content of oolong teas is comparable to green teas (13). There is little information on the caffeine content of white teas, since they are often grouped together with green teas (14). Buds and young tea leaves have been found to contain higher levels of caffeine than older leaves (15), suggesting that the caffeine content of some white teas may be slightly higher than that of green teas (16).

Table 2. Caffeine Content of Teas and Coffee (12, 14, 17)

Type of Tea	Caffeine (mg/L)	Caffeine (mg/8 ounces)
Green	40-234	9-63
Black	177-333	42-79
Coffee, brewed	306-553	72-130

Caffeine is a known stimulant of the central nervous system, thought to protect dopaminergic neurons by antagonizing adenosine A_{2A} receptors (**Figure 5**) (18). Because adenosine has mostly inhibitory effects in the central nervous system, the effects of adenosine antagonism by caffeine are generally stimulatory.

Figure 5. Caffeine (and Adenosine)



Fluoride

Tea plants accumulate fluoride in their leaves. In general, the oldest tea leaves contain the most fluoride (19). Most high-quality teas are made from the bud or the first two to four leaves — the youngest leaves on the plant. Fluoride levels in green, oolong, and black teas are generally comparable to those recommended for the prevention of dental caries (cavities). Thus, daily consumption of up to one liter of green, oolong, black, or pu-erh tea would be unlikely to result in fluoride intakes higher than those recommended for dental health (20, 21). The fluoride content of white tea is likely to be less than other teas, since white teas are made from the buds and youngest leaves of the tea plant. A comparative study of green, oolong, and black teas from six provinces of China found that fluoride content was inversely correlated with the quality level of tea sensory attributes (i.e., appearance, taste, flavor) (22). The fluoride content of 17 brands of green, oolong, and black teas is presented in **Table 3** (20). These values do not include the fluoride content of the water used to make the tea. For more information, see the article on Fluoride.

Table 3. Fluoride Content of Teas (21)

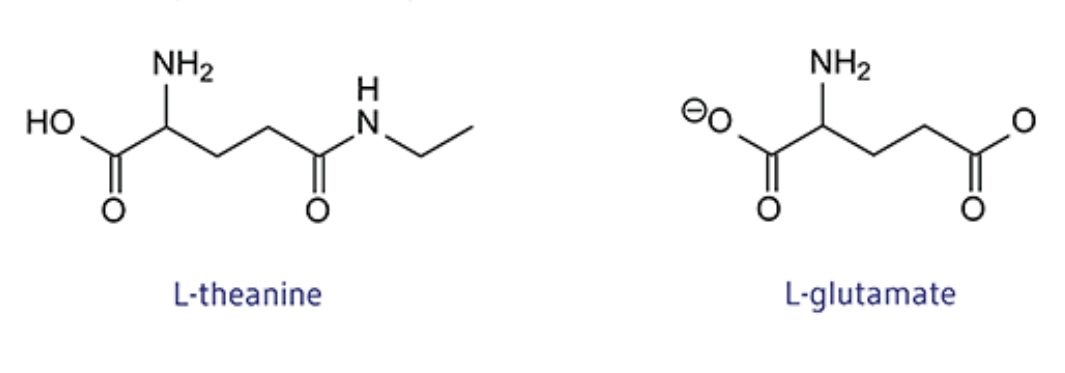
Type of Tea	Fluoride (mg/liter)[1]	Fluoride (mg/8 ounces)
Green	1.2-1.7	0.3-0.4
Oolong	0.6-1.0	0.1-0.2
Black	1.0-1.9	0.2-0.5
Pu-erh tea	0.9-1.6	0.2-0.4

[1] Fluoride in 1% weight/volume tea prepared by continuous infusion from 5 minutes (number before hyphen) to 360 minutes (number after hyphen).

L-theanine

L-theanine (also L-g-glutamylethylamide) is a non-protein amino acid that constitutes about 1%-2% (w/w) of *Camellia sinensis* dry leaves (23). L-theanine is rapidly absorbed in the small intestine and has a bioavailability close to 100% (24). L-theanine can cross the blood-brain barrier and exert neuroprotective effects (25). Because its chemical structure resembles that of glutamate, a neurotransmitter critically involved in memory, theanine may compete with glutamate for binding to glutamate receptors (**Figure 6**). This glutamate antagonism has been associated with the prevention of neuronal death by theanine after brain ischemia (reviewed in 25).

Figure 6. Theanine (and Glutamate)



Disease Prevention

Cardiovascular disease

Many epidemiological studies have considered the relationship between tea consumption and manifestations of cardiovascular disease (CVD), including coronary heart disease (CHD) and stroke (reviewed in 26). A recent meta-analysis by Zhang et al. included the results of prospective observational studies (cohort or nested case-control studies) that examined the association between tea consumption and cardiovascular morbidity and mortality (27). The results showed that a three-cup (125 mL/cup) increase in daily tea intake was associated with a 27% lower risk of CHD (seven studies), an 18% lower risk of total stroke (eight studies), a 16% lower risk of ischemic stroke (four studies), a 21% lower risk of intracerebral hemorrhage (a type of hemorrhagic stroke), a 26% lower risk of cardiac deaths (12 studies), and a 24% lower risk of total deaths (seven studies). No associations were found between tea consumption and stroke mortality (five studies) or risk of subarachnoid hemorrhage (a subtype of stroke; two studies). Further subgroup analyses indicated that green tea consumption was specifically linked to a reduced risk of stroke, cardiac mortality, and all-cause mortality, while a lower CHD risk was associated with black tea consumption (27). Another recent meta-analysis of prospective cohort studies found that the highest versus lowest level of green tea consumption was associated with a 33% lower risk of cardiovascular mortality (five studies) and a 20% lower risk of all-cause mortality (five studies) (28). Black tea consumption was linked to a 10% reduced risk of all-cause mortality, but not specifically to cardiovascular-related mortality (28).

Tea is a major source of flavonoids in US and European diets (29, 30). The results of several epidemiological studies suggest that dietary flavonoids might influence cardiovascular health. A recent meta-analysis of 14 prospective cohort studies reported that highest versus lowest quantiles of flavonol, flavan-3-ol, flavanone, flavone, anthocyanidin, and proanthocyanidin intake were associated with modest reductions (~10%) in cardiovascular risk (31). A dose-response analysis based on the results of 13 studies in nearly 350,000 individuals and 12,445 CVD cases found a 5% risk reduction with an average 10 mg-incremental increase in daily flavonol intakes (31). It is not clear whether the antioxidant, anti-inflammatory, and/or vasodilatory properties of flavonoids are responsible for some of the cardiovascular benefits associated with tea consumption (see also the article on Flavonoids).

Intervention studies

A number of intervention trials have investigated the effects of tea consumption on markers of cardiovascular health, including biological parameters related to lipid and glucose metabolism, inflammation, blood coagulation, endothelial health, and body composition.

Metabolic markers of cardiovascular disease: Clinical trials examining the effects of green and/or black tea beverages or extracts have been relatively heterogeneous, especially regarding concentrations of active substances, duration of interventions, and included populations. Pooled analyses of mostly short-term interventions (<3 months) have suggested a reduction in total and LDL cholesterol concentrations with green tea catechin consumption, but the data regarding a potential lipid-lowering effect of black tea are inconsistent (32-34).The studies mentioned below investigated the effect of tea/tea extracts given for at least three months.

Black tea: The Tea's Effect on Atherosclerosis (TEA) pilot study in 28 older adults at increased risk for cardiovascular disease (CVD) did not find any effect of a six-month black tea consumption intervention (three glasses per day equivalent to 318 mg/day of black tea catechins) on specific biomarkers, including circulating lipoproteins, inflammation markers, homocysteine concentration, adhesion molecules, and hemostatic factors (35). Yet, in a randomized, placebo-controlled study in 47 individuals with borderline-to-moderate hypercholesterolemia, the daily consumption of 1 g of pu-erh tea (Chinese black tea) extract for three months reduced the blood concentrations of total cholesterol, LDL-cholesterol, and triglycerides (36). A three-month, placebo-controlled trial in 77 healthy subjects who drank 9 g of black tea infused in 600 mL of boiling water per day (about 740 mg/day of black tea polyphenols) had improvements in lipoprotein and triglyceride profiles, fasting serum glucose concentrations, and measures of antioxidant activities in the plasma (37). The same protocol was found to also reduce markers of oxidative stress and inflammation in the plasma of individuals at risk for CVD (38). In contrast, a recent randomized, double-blind, placebo-controlled trial in 77 regular tea drinkers (35 to 75 years old) found that the daily consumption of 429 mg of black tea polyphenols for six months had no effect on fasting blood glucose and serum lipids (39).

Green tea: Daily supplementation with a capsule containing 150 mg of green tea catechins, 75 mg of black tea theaflavins, and 150 mg of other polyphenols, for six months significantly lowered plasma LDL-cholesterol concentrations and the ratio total cholesterol:HDL in a randomized, double-blind, placebo-controlled study in 220 individuals with mild-to-moderate hypercholesterolemia (40). In a pilot study in 74 overweight/obese breast cancer survivors, the daily consumption of green tea (containing 26.7 mg of caffeine and 235.6 mg of catechins with 128.8 mg as EGCG) for six months increased HDL concentration compared to a citrus-based herbal placebo but had no effect on LDL concentration and markers of glycemic control (41). Another placebo-controlled study conducted in obese subjects with controlled hypertension found that the daily ingestion of one capsule of green tea extract (379 mg/capsule containing 208 mg of EGCG) for three months significantly lowered systolic and diastolic blood pressure and improved blood lipid profile, antioxidant status, and measures of glycemic control and inflammation (42).

Endothelial dysfunction: The vascular endothelial cells that line the inner surface of all blood vessels synthesize an enzyme, endothelial nitric oxide synthase (eNOS), which plays a critical role in maintaining cardiovascular health. Specifically, eNOS utilizes L-arginine to produce nitric oxide (NO), a compound that regulates vascular tone and blood flow by promoting the relaxation (vasodilation) of all types of blood vessels, including arteries (26). NO also regulates vascular homeostasis and protects the integrity of the endothelium by inhibiting vascular inflammation, leukocyte adhesion, platelet adhesion and aggregation, and proliferation of vascular smooth muscle cells (43). In the presence of cardiovascular risk factors (e.g., hypertension, hypercholesterolemia, hyperglycemia), early alterations in the structure and function of the vascular endothelium are associated with the loss of normal NO-mediated endothelium-dependent vasodilation. Endothelial dysfunction results in widespread vasoconstriction and coagulation abnormalities and is considered to be an early step in the development of atherosclerosis. The measurement of brachial flow-mediated dilation (FMD) is often used as a surrogate marker of endothelial function; FMD values are inversely correlated with the risk of future cardiovascular events (44).

Black tea: Two small controlled clinical trials found that daily consumption of 900 to 1,250 mL of black tea for four weeks significantly improved endothelium-dependent FMD in patients with coronary heart disease (45) and in patients with mildly elevated serum cholesterol concentrations (46). Improvements were noted in comparison to an equivalent amount of hot water. Incremental doses of black tea flavonoids (0, 100, 200, 400, and 800 mg/day; each dose being given for one week) have been associated with dose-dependent increases in brachial FMD in 19 healthy volunteers. Specifically, FMD values went from 7.8% at baseline (no flavonoids) to 10.3% with 800 mg/day of flavonoids (47). Of note, in this study, the ingestion of black tea flavonoids significantly lowered systolic and diastolic blood pressure in a non dose-dependent manner, while other variables, including markers of arterial stiffness, glucose metabolism, inflammation, endothelial activation, and lipid profile, remain largely unchanged (47). In a recent randomized trial, seven days of black tea consumption (450 mL/day) followed by the ingestion of two cups (300 mL) 20 minutes before an experimental ischemia-reperfusion (IR) injury procedure on healthy participants failed to prevent IR injury-associated FMD reduction. Even if tea flavonoids were able to limit the impact of IR injury on FMD — for example by counteracting the production of reactive oxygen species — the presence of caffeine in black tea (and the lack of control for it) could have confounded this effect (48).

Green tea: In a small study conducted in 14 healthy young adults (50% smokers), a significant increase in brachial FMD was reported 30 to 120 minutes after the consumption of 450 mL of green tea (6 g of green tea, including 125 mg of caffeine) compared to caffeine alone or hot water (49). Another study that compared the acute effect of black and green tea on brachial FMD in 21 postmenopausal women found a similar increase in FMD two hours after the ingestion of either tea preparation (50). Both black and green teas have been found to be equally able to increase eNOS activity and NO production in cultured endothelial cells (50, 51). Specifically, the prominent green tea catechin, EGCG, and black tea polyphenols, theaflavins and thearubigins, are thought to contribute to the protective effect of drinking tea by promoting antioxidant activity and endothelium-dependent vasodilation (51). Other flavonoids, like (-)-epicatechin and quercetin glucoside have recently failed to show an effect on FMD (and blood pressure) in hypertensive adults (52). For more information, see the article on Flavonoids.

A meta-analysis of nine human intervention studies estimated that the acute and/or short-term (up to four weeks), daily ingestion of 500 mL of tea — containing about 248 mg of flavonoids in green tea and 415 mg in black tea — significantly increased brachial FMD (53). Yet, the clinical relevance of these FMD improvements is unclear. It is also not clear whether the chronic consumption of tea might benefit vascular endothelial function and eventually lower the risk of cardiovascular disease.

Hypertension: Hypertension (high blood pressure) is a risk factor for CVD morbidity and mortality.

Black tea: A recent meta-analysis of 11 small randomized controlled trials in either healthy or at-risk individuals found a significant reduction of 2 mm Hg in systolic and 1 mm Hg in diastolic blood pressure with the daily consumption of at least 400 mL (13 oz) of black tea for one week to six months, providing a minimum of 240 mg/day of flavonoids (54). Two recent trials also reported that black tea lowered the rate of circadian variations in blood pressure at nighttime and variations after a dietary fat challenge. A six-month intervention in 76 participants from the general population (most with moderate hypertension) showed that the consumption of three cups per day of black tea, supplying a daily total of 1.29 g of polyphenols and 288 mg of caffeine, lowered the rate of nighttime blood pressure variations compared to a polyphenol-free caffeine-matched placebo (55). Two cups of black tea per day, equivalent to 300 mg of polyphenols, also limited blood pressure variations after a fat-rich meal in 19 patients with primary (idiopathic) hypertension (56). Mechanisms underlying the blood pressure-lowering properties of black tea may involve the inhibition of angiotensin-II synthesis by flavonoids (see below).

Green tea: Several recent meta-analyses of randomized controlled trials indicated that the consumption of green tea or green tea extracts could significantly lower blood pressure (57-60). In one of them, the pooled analysis of 13 trials in 1,367 subjects found a 2.0 mm Hg reduction in systolic blood pressure and a 1.9 mm Hg reduction in diastolic blood pressure with green tea polyphenols (208 mg/day-1,207 mg/day) for a median period of 12 weeks (60). Subgroup analyses suggested greater blood pressure lowering effect with polyphenol intake levels lower than 582.8 mg/day and with adjustment for the confounding effect of caffeine. Another meta-analysis included randomized controlled trials that specifically explored the effect of green tea or green tea extracts on blood pressure in overweight or obese subjects. The pooled analysis of 14 trials showed significant reductions of 1.4 mm Hg in systolic blood pressure and 1.3 mm Hg in diastolic blood pressure (58). The anti-hypertensive effect of green tea may be mediated by a number of mechanisms. For example, pharmacological concentrations of several catechins have been shown to inhibit the activity of a key regulator of arterial blood pressure, angiotensin-converting enzyme (ACE), *in vitro* (61). ACE catalyzes the conversion of angiotensin-I into angiotensin-II, a potent inducer of vasoconstriction. In addition, studies in rats showed that chronic treatment with epicatechin prevented salt-induced hypertension, partly through inhibition of endothelin-1 expression and NADPH oxidase (NOX) activity (62). Other potential benefits of green tea consumption, including improvements in blood lipid profile, insulin sensitivity, and endothelial function, may also contribute to its blood pressure-lowering effects.

Type 2 diabetes mellitus

Impaired glucose tolerance in patients with prediabetes is often associated with loss of insulin sensitivity, impaired lipid metabolism, low-grade inflammation, and endothelial dysfunction (63). Without changes in lifestyle behavior (especially regarding dietary habits and physical activity), individuals with prediabetes will eventually progress to develop overt type 2 diabetes mellitus (64).

In this context, the association between tea consumption and risk of type 2 diabetes has been examined in a recent European, multicenter, nested case-control study — the "EPIC-InterAct" project — that included 16,835 diabetes-free participants and 12,043 individuals with diabetes (65). The results showed that tea consumption was inversely associated with diabetes incidence. The consumption of four cups per day rather than none was found to be associated with a 16% lower risk of diabetes (65). Of note, in a meta-analysis of 15 prospective cohort studies, including the EPIC-InterAct study, an incremental increase of two cups per day in tea consumption was found to be associated with an estimated 4.6% risk reduction (66). The EPIC-InterAct study also found that participants in the highest quintile (>608.1 mg/day) of total flavonoid intake had a 10% lower risk of diabetes than those in the lowest quintile (<178.2 mg/day) (67). Specifically, the risk of diabetes was inversely correlated with the consumption of flavan-3-ols (catechins, proanthocyanidins, and theaflavins) and flavonols (67, 68). The intakes of other flavonoid subclasses that are less abundant in tea, namely anthocyanidins, flavanones, flavones, and isoflavones, were not associated with a reduced risk of diabetes (67).

Recent meta-analyses of randomized controlled trials that examined the possible health benefits of green tea catechins on glucose metabolism have provided conflicting results. A meta-analysis of seven trials in prediabetic and diabetic patients found no effect of green tea or green tea extracts on fasting plasma glucose, fasting serum insulin, or measures of glycemic control (HbA1c) and insulin sensitivity (HOMA-IR) (69). Conversely, another meta-analysis of 17 trials in prediabetic, diabetic, or overweight/obese subjects found that administration of green tea extracts for 4 to 16 weeks improved fasting plasma glucose and HbA1c levels (70). The effect on fasting glucose was observed only with high doses of catechins (≥457 mg/day) and when the confounding effect of caffeine was removed. However, a third meta-analysis of 25 trials found that ingestion of green tea extracts for at least two weeks could lower fasting blood glucose in both the presence or absence of caffeine (71).

Overweight and obesity

A recent meta-analysis of five small, randomized controlled trials (<100 participants per study) found that regular consumption of green or pu-erh tea extracts reduced body weight and body mass index (BMI) in overweight/obese participants with metabolic syndrome (72). The influence of green tea on body composition may be attributed to the regulation of appetite, fat absorption, fatty acid oxidation, and thermogenesis by catechins and caffeine (73). Yet, studies in overweight/obese people who are otherwise healthy have provided mixed results (reviewed in 74). Intervention studies in Caucasian populations have shown a less favorable effect of green tea catechins on body weight and energy expenditure compared to those conducted in Asian subjects. These discrepancies suggested that differences in genetic background, body composition, and dietary habits (including caffeine consumption) might interfere with the possible anti-obesity effect of green tea consumption. Large-scale, intervention trials that control for energy intake and physical activity are needed to determine if tea or tea extracts promote weight loss or improve weight maintenance in different populations with obesity and/or metabolic syndrome (74).

Cancer

Tea and tea constituents have been found to have cancer preventive activities in a variety of animal models of cancer, such as cancer of lung, mouth, esophagus, stomach, colon, and prostate (75). However, the results of epidemiological studies in humans have been mostly inconclusive.

Breast cancer

An early meta-analysis of prospective cohort studies had reported that black tea intake (five cohorts) — but not green tea (three cohorts) — was associated with a 15% higher risk of breast cancer (76). The relationship between tea consumption and breast cancer has been recently examined in the Swedish Women's Lifestyle and Health prospective cohort Study (WLHS), which followed 42,099 women for 20 years and documented 1,395 breast cancer cases (77). The results indicated a 14% higher risk of breast cancer with each cup (200 mL) of tea consumed daily. The risk was specifically increased in postmenopausal women rather than in premenopausal women. Similarly, in a recent case-control study in Chinese women in Hong Kong, regular tea consumption was inversely correlated with breast cancer risk in premenopausal women but associated with an increased risk in postmenopausal women (78). The risk associated with consuming tea was also significantly higher for estrogen- and progesterone-receptor-positive (ER+/PR+) breast cancer type in the Swedish cohort, while the highest risk was found in women with ER-negative tumors in the Chinese study (77, 78). Yet, in the European Prospective Investigation into Nutrition and Cancer Study (EPIC) in 335,060 women followed for 11 years (10,198 incidental breast cancer cases), tea intake was not associated with breast cancer overall or when the data were analyzed for menopausal status or breast cancer type (79). The most recent meta-analysis of prospective cohort studies found no association between consumption of green or black tea and breast cancer (80). Thus, current epidemiological evidence does not suggest a benefit of tea in breast cancer prevention despite promising data from cultured cells and rodent models (81).

However, some observational studies found that consumption of certain subclasses of flavonoids might have the potential to reduce the incidence of breast cancer in postmenopausal women (82). Recently, the effects of decaffeinated green tea extracts on biomarkers of breast cancer risk were examined in the Minnesota Green Tea Trial (MGTT) in 1,075 high-risk postmenopausal women randomized to receive the equivalent of four 8-ounce mugs/day (960 mL/day) in green tea extracts (1,315±116 mg/day of catechins) or a placebo for one year (83). The results have yet to be published.

Mouth, throat, and esophageal cancers

In the large, prospective NIH-AARP Diet and Health study (1995-2006) in 481,563 US adults, 1,305 cases of oral (392), pharyngeal (178), laryngeal (307), and esophageal (428) cancers have been identified during the follow-up period (84). The highest versus lowest level of tea intake (≥1 cup/day vs. non-consumption) was correlated with a 63% lower risk of pharyngeal cancer but with no other above-cited cancer types (84). Observational studies do not currently provide clear evidence for an association between tea consumption and laryngeal (85) or esophageal (86) cancers. In the case of esophageal cancer, the consumption of high-temperature beverages (including very hot tea) might even damage the epithelium and increase the risk of cancer (87). High temperature may act as a confounding factor that complicates the interaction between tea consumption and esophageal cancer (88). In 2009, a phase II, randomized, double-blind trial was conducted in 41 patients with high-risk oral premalignant lesions (OPLs). Participants were randomly assigned to orally receive 0.5, 0.75, or 1 g of green tea extract per m^2 (body surface area) or a placebo, thrice a day for three months. While the results suggested that OPLs might be clinically responsive to green tea extract treatment, larger trial populations are needed to confirm these preliminary data (89).

Gastric cancer

Several prospective cohort studies reported no association between tea consumption and risk of gastric cancer (90-92), including the US NIH-AARP Diet and Health study (84). Tea consumption also failed to predict gastric cancer cases in the EPIC study, which followed 477,312 participants and identified 683 cases during a median 11.6 years of follow-up (93). Yet, a decreased risk of intestinal type gastric cancer was observed in women in the highest versus lowest quartile of tea consumption (≥475 mL/day vs. ≤21 mL/day). Interestingly, women (but not men) in the highest versus lowest quartile of flavonol, flavanol, theaflavin, or total flavonoid intakes had a significantly reduced risk of developing gastric cancer (94). A pooled analysis of six Japanese cohort studies, including 219,080 total participants and 3,577 cases, found an inverse association between green tea consumption and gastric cancer in women but not in men: daily consumption of at least five cups of tea was associated with a 21% lower risk of gastric cancer in women compared to low intakes (<1 cup/day) (95).

Gynecologic cancers

Meta-analyses of case-control studies have found a significant 34% reduction in risk of ovarian cancer for highest versus lowest intake of green tea (four studies) (96), but no association was observed for black tea (six studies) (97). Yet, a meta-analysis of six prospective studies showed an inverse relationship between black tea consumption and ovarian cancer (98). A recent analysis of the Nurses' Health Studies (NHS I and II) showed a 31% lower risk of ovarian cancer in women consuming at least 1 cup/day compared to rare/non-black tea drinkers (99). In a prospective study in 244 women diagnosed with ovarian cancer and followed for over three years, green tea consumption was associated with a mean survival time greater for consumers (5.39 years) than for non-consumers (4.19 years) (100). However, in a single-arm, phase II trial in 16 women in complete remission from advanced stage ovarian cancer, the daily intake of 500 mL of green tea (containing 319.8 mg of EGCG) failed to effectively prevent cancer recurrence within the 18-month follow-up period (101). Further, a recent systematic review and meta-analysis of observational studies suggested a possible benefit of green tea — but not black tea — for endometrial cancer (102).

Additional studies have examined the association between tea consumption and risk of lung, prostate, liver, or colorectal cancer in humans, providing mixed results (reviewed in 103).

Bone health and osteoporosis

The etiology of osteoporosis is complex, involving factors such as aging, decreased sex hormones, inadequate nutrition, physical inactivity, genetic predisposition, as well as socioeconomic determinants. Tea bioactive components, including flavonoids, caffeine, and fluoride, have the potential to influence health and the risk of osteoporosis and fracture (104, 105). A small prospective study in 164 elderly women found that consumption of tea limited the age-related loss in total hip bone mineral density (BMD) over a four-year follow-up period (106). Also, in a six-month randomized, placebo-controlled trial in 171 postmenopausal women with osteopenia, the daily consumption of green tea catechins (500 mg) alone or combined with Tai Chi exercise (3 hours/week) improved bone turnover by stimulating bone formation (107).

Hip fracture is one of the most serious consequences of osteoporosis. A recent prospective study in 1,188 elderly women (mean age, 80 years) followed for 10 years found that participants in the highest versus lowest tertile of tea consumption (≥3 cups/day vs. ≤1 cup/week) had a 30% lower risk of any osteoporotic fracture. However, no interaction was found when the analysis was conducted on major fractures (hip, spine, humerus, and wrist) or hip fractures only (108). Yet, a meta-analysis based on 147,488 individuals from 11 observational studies published between 1990 and 2010 suggested that the consumption of 1-4 cups/day was associated with a significantly lower risk of hip fracture (109). The results of another recent meta-analysis of mostly case-control studies did not suggest any interaction between tea consumption and risk of any fracture or hip fracture (110). Additional studies are required to determine whether tea consumption affects the development of osteoporosis or the risk of osteoporotic fracture in a meaningful way.

Dental health

The cross-sectional analysis of the Ohsaki prospective cohort study that included data from 25,078 Japanese participants found an inverse association between the daily consumption of at least one cup of tea and the risk of tooth loss (111). Specifically, the risk of tooth loss was 11% lower in women and 23% lower in men who consumed at least five cups per day of tea compared to those drinking less than one cup per day. An earlier cross-sectional study of more than 6,000 14-year old children in the UK found that those who drank tea had significantly fewer dental caries than coffee drinkers; results were independent of the amount of beverage consumed or whether sugar was added (112). Although tea is a good source of fluoride — a recognized anticaries agent — both flavonoids and tannins in tea have been shown to have antimicrobial properties (reviewed in 113). Oral bacteria like *Streptococcus mutans* and *Porphyromonas gingivalis* have been associated with plaque formation, dental caries, and periodontal (gum) diseases. Untreated caries and gum inflammation can lead to severe pain, local infection, tooth loss or extraction, nutritional problems, and serious systemic infections in susceptible individuals. A pilot study in 25 adults suggested that mouthwash with a 2% green tea solution could lower acidity level and *Streptococcus mutans* count in saliva and plaque and improve measures of gum bleeding after exposure to sugar (114). A small, randomized study in 66 young volunteers (12-18 years old) also reported a significant antibacterial effect of a mouth rinse made with pulverized tea leaves compared to a placebo solution (115). Recent randomized, double-blind, controlled studies demonstrated further that tea extract-containing mouthwashes could benefit dental health and offer a possible alternative to current chlorhexidine- and fluoride-containing rinsing solutions (116-118). Finally, the incorporation of tea extract in toothpastes was found to be as effective — if not better — than regular pastes (containing fluoride and triclosan) to reduce dental plaque and gum inflammation in patients with mild to moderate periodontitis (119).

For more information on dental caries, see the article on Fluoride.

Kidney stones

The formation of kidney stones, usually composed of calcium oxalate or calcium phosphate, is a common condition that affects 7% of US women and 11% of US men during their lifetime (120). A pooled analysis of three ongoing prospective cohort studies — the Health Professionals Follow-up Study and the Nurses' Health Studies I and II, including a total of 194,095 participants — found that the risk of developing symptomatic kidney stones was 11% lower in individuals consuming at least one 8-ounce mug of tea per day compared to those consuming less than one cup per week (121). High fluid intake, including tea intake, is generally considered the most effective and economical means of preventing kidney stones (122). However, the finding that black tea may contain high amounts of oxalate (48 to 92 mg/100 mL) suggested that black tea consumption may increase urinary oxalate concentrations, a risk factor for calcium oxalate stone formation (123). The Academy of Nutrition and Dietetics recommends that kidney stone patients restrict oxalate intake to 40 mg/day-50 mg/day, and some experts advise those with a history of calcium oxalate stones to limit the consumption of oxalate-rich food, including black (but not green) tea (123, 124). Yet, recent studies have reported amounts of oxalate in different samples of green teas (0.8 to 14 mg/100 mL) (125) and black teas (1 to 2.6 mg/100 mL) (126, 127) much lower than previously published, suggesting that tea consumption would not increase kidney stone incidence or recurrence.

Mood

The term "mood" refers to an emotional state of mind that includes aspects like contentedness, relaxation, alertness, energy, and relief from depression, anxiety, and feelings of guilt and failure (128). Clinical depression is described as a mood disorder. An analysis of the NIH-AARP Diet and Health Study (1995-2006) in 263,923 participants — of which 11,311 self-reported depression — found that consumption of decaffeinated (but not caffeinated) hot tea was associated with an increased risk for depression (129). However, smaller cohort studies had previously recorded significantly less depressive symptoms in participants with higher versus lower intakes of tea (130, 131).

Tea consumption may have short-term effects on mood. In a recent cross-sectional study in 95 university staff members, consumption of tea recorded during 10 working days was associated with self reports of feeling less tired and performing better at work (132). Tea was also found to increase the positive valence of mood immediately after consumption in a small randomized controlled study in 150 participants (133).

Cognitive function

Cognitive function includes the domains of attention, memory, processing speed, and executive function, which decline gradually with increasing age.

Cognitive performance

A few studies investigated whether tea consumption was associated with cognitive benefits, especially in the domain of attention (reviewed in 134). Two cross-over, randomized, double-blind, placebo-controlled studies evaluated the effects of two servings of black tea over the course of 60 min (study 1; 26 volunteers) or three servings of black tea over the course of 90 min (study 2; 32 volunteers) on measures of attention and alertness (135). Both studies reported improved performance on objective attention tests and self-reported alertness with black tea compared to placebo. In a small open-label study, 19 participants were asked to consume either black tea (with/without caffeine), coffee (with caffeine), or water (with/without caffeine) before undergoing a battery of psychometric tests (136). Most of the improvements in cognitive function (measured with the Critical Flicker Fusion Threshold [CFFT] task) and subjective alertness were attributed to caffeine in the beverages. In addition, CFFT task scores were greater after consumption of caffeinated tea compared to caffeinated water (136). In a follow-up study, caffeinated tea outperformed caffeinated coffee in the CFFT test, suggesting that tea ingredients other than caffeine might have acute effects on cognitive function (137). A recent meta-analysis of small, randomized controlled trials (<50 participants/trial) that measured the acute effect of L-theanine (36 mg-250 mg) with or without caffeine (40 mg-250 mg) suggested an increase in alertness and attention-switching accuracy but no change regarding other parameters, such as calmness, contentedness, or anxiety (138).

Cognitive decline

The cross-sectional data analysis of 2,501 participants (≥55 years old) in the Singapore Longitudinal Ageing Study (SLAS) indicated that higher intakes of tea correlated with better global cognitive function, as assessed by Mini-Mental State Examination (MMSE) scores (139). Conversely, lower levels of tea consumption were associated with a higher prevalence of cognitive impairments, defined as MMSE scores ≤23. Similar observations have been reported in several other cross-sectional studies (140-143). In the SLAS study, the follow-up of 1,438 cognitively healthy people for one to two years showed that the risk of cognitive decline (defined as a drop of ≥1 point in the MMSE score) was up to 43% lower in tea drinkers compared to non-drinkers (139). Further research in 716 SLAS participants (mean age, 64.5 years) with normal cognitive function confirmed that those consuming tea scored higher in the MMSE global cognition test than non-consumers. Tea consumption was also correlated with higher cognitive test scores regarding memory, executive function, and information-processing speed (144). Tea consumption was also modestly associated with a reduced risk of cognitive decline in 2,722 women (but not in men) followed for a median 7.9 years in the US population-based Cardiovascular Health Study, despite a much lower frequency of tea consumption (up to 5 cups/week) than that observed in the SLAS (over 10 cups/day) (145). In a prospective cohort study in Japanese older people (>60 years old) followed for nearly five years, daily green tea consumers were shown to have lower risks of mild cognitive impairments (MCI) and dementia compared to non-consumers (146). In a recent pilot trial, the consumption of green tea extracts (2 g/day, of which 227 mg of catechins and 42 mg of theanine) for three months resulted in higher MMSE scores (compared to baseline) due to improved short-term memory scores in 12 elderly nursing home residents (ages, 70 to 98 years) with symptoms from MCI to severe dementia (147).

Long-term, large randomized controlled trials are needed to establish whether tea or its bioactive components could limit cognitive decline and/or improve cognitive dysfunction in older individuals.

Parkinson's disease

Parkinson's disease (PD) is a neurodegenerative disease characterized by the selective death of dopaminergic brain cells in the substantia nigra. PD is estimated to affect 0.5%-4% of older people (≥65 years old) worldwide (148). A retrospective study in 279 subjects with PD suggested that the onset of motor symptoms in those drinking more than 3 cups/day of tea was delayed by several years compared to nondrinkers (149); yet, after disease onset, a similar rate of disease progression was observed among tea drinkers and non-drinkers (150). A meta-analysis of eight case-control studies, including 4,250 controls and 1,418 PD cases, found a 15% reduced risk of PD with higher versus lower intake of tea (151). Another meta-analysis of four case-control studies and four prospective cohort studies published between 1999 and 2012 indicated that individuals in the highest category of tea consumption had a 37% lower risk of PD compared to those in the lowest category (152). The authors estimated that each 2 cups/day-increase in tea consumption was associated with a 26% lower risk of developing PD (152). If a protective effect of tea consumption can be further demonstrated, several bioactive compounds, especially caffeine (153) and flavonoids (154), could be responsible for the tea benefits in PD prevention.

Safety

Adverse effects

Tea

Tea is generally considered to be safe, even in large amounts. However, two cases of hypokalemia (abnormally low serum potassium concentrations) in the elderly have been attributed to excessive consumption of black and oolong tea (3 L/day-14 L/day) (155, 156). Hypokalemia is a potentially life-threatening condition that has been associated with caffeine toxicity (157, 158). Case reports of stomach cramps (159), kidney stones (160), and skeletal fluorosis (161-163) due to excessive tea consumption have also been published.

Tea extracts

In clinical trials employing caffeinated green tea extracts, cancer patients who took 6 g/day, in three to six divided doses, experienced mild-to-moderate gastrointestinal side effects, including nausea, vomiting, abdominal pain, and diarrhea (164, 165). Central nervous system symptoms, including agitation, restlessness, insomnia, tremors, dizziness, and confusion, have also been reported. In one case, confusion was severe enough to require hospitalization (164). In a systematic review published in 2008, the US Pharmacopeia (USP) Dietary Supplement Information Expert Committee identified 34 adverse event reports implicating the use of green tea extract products (containing 25%-97% of polyphenols) as the likely cause of liver damage (hepatotoxicity) in humans (166). Nineteen additional cases of hepatotoxicity associated with the consumption of herbal products containing green tea have been reported for the period 2008-2015 (167). In a four-week clinical trial that assessed the safety of decaffeinated green tea extracts (800 mg/day of EGCG) in healthy individuals, a few of the participants reported mild nausea, stomach upset, dizziness, or muscle pain (168). In the Minnesota Green Tea Trial (MGTT), 1,075 postmenopausal women were randomized to receive green tea extracts (1,315±116 mg/day of catechins; the equivalent of four 8-ounce mugs of brewed decaffeinated green tea) or a placebo for one year. The total number of adverse events and the number of serious adverse events were not different between the treatment and placebo groups (169). However, the use of green tea extracts was directly associated with abnormally high liver enzyme levels in 7 out of the 12 women who experienced serious adverse events. Also, the incidence of nausea was twice as high in the green tea arm as in the placebo group (169).

Pregnancy and lactation

The safety of tea extracts or supplements for pregnant or breast-feeding women has not been established. Some organizations, like the American College of Obstetricians and Gynecologists, suggest to limit caffeine consumption during pregnancy to less than 200 mg/day (170), because higher caffeine intakes have been associated with increased risk of miscarriage and low birth weight in some epidemiological studies (171, 172).

Drug interactions

Green tea

Excessive green tea consumption may decrease the therapeutic effects of the anticoagulant, warfarin (Coumadin, Jantoven). Such an effect was documented in only one patient who began drinking one-half gallon to one gallon of green tea daily (173). It is probably not necessary for people on warfarin therapy to avoid green tea entirely; however, large quantities of green tea may increase the risk of bleeding in warfarin-treated patients (174). Green tea extracts may also reduce the efficacy or increase the toxicity of at least two other cardiovascular drugs, namely simvastatin (Zocor) and nadolol (Corgard) (175). Preclinical studies suggested that green tea extracts may interfere with drug metabolism by affecting the activity of cytochrome P450 3A4 (CYP3A4), which catalyzes the metabolism of about one-half of all marketed drugs in the US and Canada (176). Additional information on drug interactions is available in the article on Flavonoids.

Caffeine

A number of drugs can impair the metabolism of caffeine, increasing the potential for adverse effects from caffeine (177). Such drugs include cimetidine (Tagamet), disulfiram (Antabuse), estrogens, fluoroquinolone antibiotics (e.g., ciprofloxacin, enoxacin, norfloxacin), fluconazole (Diflucan), fluvoxamine (Luvox), mexiletine (Mexitil), riluzole (Rilutek), terbinafine (Lamisil), and verapamil (Calan). High caffeine intakes may increase the risk of toxicity of some drugs, including albuterol (Ventolin), metaproterenol (Alupent), clozapine (Clozaril), ephedrine, stimulant drugs (e.g., epinephrine), monoamine oxidase inhibitors, phenylpropanolamine, and theophylline. High caffeine intakes may also reduce the bioavailability and/or the efficacy of drugs like carbamazepine, valproate, dipyridamole (Persantine), pentobarbital (Nembutal), and phenobarbital (Luminal). Abrupt caffeine withdrawal has been found to increase serum lithium levels in people taking lithium, potentially increasing the risk of lithium toxicity.

Nutrient interactions

Iron

Flavonoids in tea can bind nonheme iron, inhibiting its intestinal absorption (178, 179). Nonheme iron is the principal form of iron in plant foods, dairy products, and iron supplements. The consumption of one cup of tea with a meal has been found to decrease the absorption of nonheme iron in that meal by about 70% (180, 181). Flavonoids can also inhibit intestinal heme iron absorption (182). Interestingly, ascorbic acid (vitamin C) greatly enhances the absorption of iron and is able to counteract the inhibitory effect of flavonoids on nonheme and heme iron absorption (179, 182, 183). To maximize iron absorption from a meal or iron supplements, subjects with poor iron status should not consumed tea at the same time (184). In addition, healthy individuals at no risk of iron deficiency do not need to restrict their consumption of tea (184, 185).

Summary

- Observational studies have consistently found that moderate alcohol consumption (no more than two alcoholic drinks/day for men and no more than one alcoholic drink/day for women) is associated with a decreased risk of cardiovascular and all-cause mortality. *(More information)*
- Moderate alcohol consumption is associated with lowered risks of coronary heart disease (CHD) and ischemic stroke. *(More information)*
- Evidence from observational studies suggests that moderate alcohol intake may be associated with reduced risk of type 2 diabetes, dementia, and gallstones, as well as with improved bone mineral density. *(More information)*
- Even moderate alcohol consumption may increase the risk of female breast cancer, alcohol-related birth defects, and progression to heavy alcohol consumption in some people. *(More information)*
- Heavy alcohol consumption is associated with increased risks of hypertension, stroke, heart rhythm disturbances, dementia, accidents, injury, violence, and damage to the heart, liver, and pancreas. *(More information)*
- Heavy alcohol consumption is associated with increased risk of many cancers, including cancers of the mouth, pharynx, larynx, esophagus, liver, breast, colon and rectum. The combined use of alcohol and tobacco greatly increases the risk of oral and esophageal cancers. *(More information)*
- Those who consume more than minimal amounts of alcohol should make sure they also consume adequate folate by taking a daily multivitamin that provides 400 μg of folic acid. *(More information)*
- There is consensus that the health risks of moderate alcohol consumption outweigh the health benefits for some people. People who should abstain from alcohol include (1, 2): children and adolescents; pregnant women and women who may become pregnant; anyone who has trouble limiting his or her alcohol consumption to moderate levels, particularly recovering alcoholics and those with a family history of alcoholism or alcohol problems; and anyone with chronic liver disease or alcohol-related disease or organ damage.
- Anyone planning to drive, operate heavy machinery, or perform other potentially hazardous activities requiring coordination and skill should not consume alcohol.
- People who would benefit from individualized advice regarding potential health risks and benefits of moderate alcohol consumption include: anyone taking medications (over-the-counter or prescription) with the potential for adverse interactions with alcohol; and anyone with a personal or family history (e.g., parent or sibling) of breast cancer, coronary heart disease, or other conditions related positively or inversely to moderate drinking.

Introduction

While excessive alcohol consumption has been linked to a number of serious health and social problems, observational studies have associated moderate alcohol consumption with some important health benefits. The relationship between alcohol consumption and mortality is often described as J-shaped, meaning that when graphed from alcohol abstinence on the left to heavy drinking on the right, light-to-moderate alcohol consumption (≤2 drinks/day) is associated with lower rates of mortality — mostly from cardiovascular disease — than abstention, while heavy alcohol consumption (>3-4 drinks/day) is associated with higher rates of mortality from a number of causes (3-5). Because the consumption of alcohol can be viewed as a "double-edged sword," individual decisions regarding alcohol use should take into consideration scientific evidence regarding potential health benefits and risks, as well as personal and family histories of health problems and addictions.

It is important to note the data on alcohol-disease relationships come from only observational studies, not randomized controlled trials, and observational data cannot establish causation. In observational research, potential confounding variables should be adequately adjusted for using statistical techniques. For instance, nondrinkers have been shown to differ from those who consume alcohol in ways that might affect the disease outcome of interest (6). Even when controlling for many potential confounders, residual confounding may still occur.

Definitions (7)

Standard alcoholic drink (8)

A standard alcoholic drink contains approximately 14 grams of alcohol, which is equivalent to 12 ounces of beer (~5% alcohol), 8.5 ounces of malt liquor (~9% alcohol), 5 ounces of wine (~12% alcohol), 3.5 ounces of fortified wine (e.g., sherry or port), or 1.5 ounces of liquor (distilled spirits; ~40% alcohol).

Moderate alcohol consumption

- **Men**: No more than two standard alcoholic drinks/day (9)
- **Women**: No more than one standard alcoholic drink/day* (9)
- There is consensus that distributing total weekly alcohol intake evenly to most days is the healthiest drinking pattern.

Heavy alcohol consumption (8)

- **Men**: More than 14 standard alcoholic drinks/week or more than 4 standard alcoholic drinks in a day
- **Women**: More than 7 standard alcoholic drinks/week or more than 3 standard alcoholic drinks in a day*

*In addition to weighing less, on average, women absorb and metabolize alcohol differently than men. In general, women have less body water than men of similar body weight, so women achieve higher blood alcohol concentrations after drinking equivalent amounts of alcohol (10). Women also appear to be more vulnerable to adverse health effects of heavy drinking than men. Thus, most definitions of "moderate" or "heavy" drinking offer a lower threshold for women.

Potential Health Benefits of Moderate Alcohol Consumption

Mortality

Data from observational studies have shown that light-to-moderate alcohol consumption (≤1 drink/day for women and ≤2 drinks/day for men) is protective against all-cause mortality (4, 11-15). As mentioned above, a J-shaped relationship is apparent when all-cause mortality is plotted against alcohol consumption (alcohol abstinence on the left and heavy drinking on the right of the x-axis) (4, 16). In other words, those who drink moderately have the lowest risk of total mortality when compared to nondrinkers and heavy drinkers, and heavy drinkers have the highest risk of mortality.

The association of reduced mortality with moderate alcohol consumption is largely attributed to a decrease in cardiovascular mortality (14, 16-18), especially from coronary heart disease (see Cardiovascular disease below). However, concern has been raised that some earlier observational studies have misclassified former drinkers in the lifetime abstention group (i.e., the referent group), but most recent studies have not supported such a 'misclassification hypothesis' (15, 16, 19).

Cardiovascular disease

Coronary heart disease

Over the past four decades, the most consistent evidence of a health benefit associated with moderate alcohol consumption has been a significant reduction in the risk of coronary heart disease (CHD) — a finding confirmed by a large number of epidemiological studies. When the results of 28 prospective cohort studies were combined in a meta-analysis, adults who consumed an average of 25 grams/day of alcohol (the amount in two standard alcoholic drinks) had a risk of CHD that was 20% lower than adults who did not consume alcohol (20). More recent data from two large prospective cohort studies conducted in the US suggest that the magnitude of CHD risk reduction associated with moderate alcohol consumption may be closer to 30%. In a 12-year study of more than 38,000 male health professionals, those who consumed alcohol at least 3-4 times weekly had a risk of myocardial infarction (heart attack) that was 32% lower than men who drank alcohol less than once weekly (21). Similarly, in a 20-year study of more than 120,000 men and women, those who reported consuming 1-2 alcoholic drinks daily had a risk of death from CHD that was 30% lower than those who did not drink alcohol (22). A 2011 systematic review and meta-analysis of 29 studies found that alcohol consumption was associated with a 29% reduced risk of CHD compared to abstention; intakes of 2.5 to 60.0 grams/day of alcohol were associated with a lower risk of CHD (16).

How does alcohol consumption reduce CHD risk? The development of CHD is characterized by the formation of cholesterol-laden plaque in the arteries (atherosclerosis), vascular inflammation, and clot formation (23). Numerous small, randomized trials have examined the effect of daily alcohol consumption on markers of CHD risk, consistently finding that moderate alcohol consumption significantly increases concentrations of high-density lipoprotein (HDL)-cholesterol — the 'good cholesterol' (24, 25). HDLs transport cholesterol from tissues, including arterial walls, back to the liver for elimination or recycling. In addition to increasing HDL levels, moderate alcohol consumption has been shown to increase apolipoprotein A1, a major component of circulating HDL (25). Higher levels of high-density lipoprotein (HDL)-cholesterol have been associated with reductions in CHD risk (26).

Alcohol may also have anti-thrombotic properties. Clot formation is the result of complex interactions between factors that promote coagulation and factors that inhibit coagulation or promote the dissolution of clots. Several randomized trials have found that moderate alcohol consumption decreases serum levels of fibrinogen, a protein that promotes clot formation (25) and increases serum levels of an enzyme that helps dissolve clots (tissue type plasminogen activator) (24).

Further, moderate alcohol consumption may have an anti-inflammatory effect since serum levels of C-reactive protein (CRP), a marker of systemic inflammation and sensitive predictor of CHD risk, are lower in people who drink moderately than those who abstain from alcohol (27-32). Moderate alcohol consumption has also been associated with improvements in adiponectin levels (25), insulin sensitivity (see Type 2 diabetes mellitus below), abdominal obesity (33), and endothelial function (34).

Does the type of alcohol consumed (wine, beer, or liquor) affect CHD risk? Significant reductions in CHD risk have been associated with moderate consumption of wine, beer, and liquor. However, the "French Paradox" — the observation that mortality from CHD is relatively low in France despite relatively high levels of dietary saturated fat and cigarette smoking — led to the idea that regular consumption of red wine might provide additional protection from CHD (35, 36). Red wine contains the phenolic compound resveratrol — although usually at variable and low concentrations (see the article on Resveratrol) — as well as flavonoids like procyanidins; these compounds could provide additional cardiovascular benefits beyond those associated with ethanol. Beer also contains polyphenolic compounds that might confer some cardioprotection (37).

Some large prospective cohort studies have found wine drinkers to be at lower risk of CHD than beer or liquor drinkers (22, 38-40), but others have found no difference (21, 41, 42). Moreover, some studies have observed a decreased risk of myocardial infarction or CHD in predominantly beer-drinking populations in the Czech Republic (43), in Germany (44), and in Japanese men residing in Hawaii (45). A 2011 meta-analysis of prospective cohort and case-control studies found that moderate consumption of wine or beer was associated with a decreased risk of non-fatal vascular events (46). This analysis did not associate drinking liquor with cardiovascular benefit, although the authors noted that binge drinking — which is known to increase CHD risk — was apparent in several of the included studies (46).

Socioeconomic status and lifestyle characteristics (e.g., tobacco use, exercise habits) may differ among people who prefer wine, beer, or liquor, and this may in part explain any additional benefit of one beverage type observed in some studies. For example, several early studies found that people who prefer wine tend to have higher incomes, have more formal education, smoke less, and eat more fruit and vegetables and less saturated fat than people who prefer other alcoholic beverages (47-49). These potential confounders should be controlled or adjusted for in the analysis of observational data.

Thus, although moderate alcohol consumption has been consistently associated with 20%-30% reductions in CHD risk, it is not yet clear whether drinking a specific type of alcoholic beverage might confer additional cardiovascular benefit.

Stroke

Ischemic strokes, which represent 87% of all strokes, are the result of insufficient blood flow to an area of the brain, which may occur when an artery supplying the brain becomes blocked by a blood clot (50). Hemorrhagic strokes occur when a blood vessel ruptures and bleeds into the brain. Although they are less prevalent than ischemic strokes, hemorrhagic strokes are generally more severe and contribute disproportionately to overall stroke mortality (51). Light or moderate alcohol consumption has been associated with a reduced risk of ischemic stroke, but not hemorrhagic stroke, in a number of observational studies (52-58). When the results of 19 prospective cohort and 16 case-control studies of alcohol consumption and the risk of stroke were combined in a meta-analysis, moderate alcohol consumption was associated with a significant reduction in the risk of ischemic stroke (59). Overall, those who consumed one or two drinks daily had a 28% lower risk of ischemic stroke than those who did not consume alcohol. Another meta-analysis of more recent studies (1980-2009) confirmed that moderate alcohol consumption was protective against only ischemic stroke in both men and women (60). A more recent meta-analysis of 27 prospective cohort studies found that light-to-moderate alcohol consumption (<15 grams/day) in women was associated with a reduced risk of ischemic (RR, 0.72) but not hemorrhagic stroke; moderate alcohol consumption (15-30 grams/day) was not linked to either type of stroke in men in this analysis (61).

Thus, light-to-moderate alcohol consumption appears to decrease risk of ischemic stroke, but not hemorrhagic stroke, likely due to the anti-thrombotic effect of alcohol.

Peripheral arterial disease

Just as atherosclerosis of the arteries supplying the heart muscle leads to coronary heart disease, atherosclerosis of the arteries of the extremities leads to peripheral arterial disease (PAD). When atherosclerosis is severe enough to diminish blood flow to the legs, even walking may result in leg or hip pain known as intermittent claudication (62). Impaired vascular endothelial function is also characteristic of the disease and may contribute to the clinical symptoms (63).

Although much less consistent than the evidence for heart disease and stroke, there is limited evidence that moderate alcohol consumption is associated with decreased risk of PAD. Four prospective cohort studies have found moderate alcohol consumption to be associated with significant decreases in several different indicators of PAD (64-67). One of these studies found that the inverse association between alcohol intake and PAD risk was significant in nonsmokers but not smokers, suggesting that the adverse effects of cigarette smoking on PAD risk may outweigh any protective effects of alcohol consumption (64).

Heart failure

Coronary heart disease is a major cause of heart failure. A prospective study in a cohort of 21,601 men and another in a cohort of 126,236 men and women found that moderate alcohol intake was inversely associated with heart failure, especially heart disease related to CHD (68, 69). More recently, in a cohort of 4,490 older adults (65 years or older at baseline) followed for more than 20 years (1,380 cases of heart failure), drinking one or more alcoholic drink per week was associated with a 26% lower risk of heart failure compared to abstainers (70).

Sudden cardiac death

While several studies have found that heavy alcohol consumption increases risk of sudden cardiac death (SCD; see below), the association of light-to-moderate alcohol consumption and SCD is less clear. Studies on this association have reported mixed results, but the two largest prospective cohort studies to date have found a lower risk of SCD with light-to-moderate alcohol consumption (71, 72).

Type 2 diabetes mellitus

Three meta-analyses have found a U-shaped relationship between alcohol consumption and incidence of type 2 diabetes mellitus, with greater protection being observed for women (73-75). The most recent meta-analysis included 20 prospective cohort studies and associated moderate alcohol consumption (22-25 grams of alcohol daily or 1.6-1.8 drinks/day) with a 40% risk reduction for women and a 13% risk reduction for men compared to lifetime alcohol abstainers (74). Heavy alcohol consumption (62 grams/day or 4.4. drinks/day for men and 51 grams/day or 3.6 drinks/day for women) was associated with an increased risk for type 2 diabetes (74).

Increased insulin secretion by the pancreas and decreased insulin sensitivity are important factors leading to the development of type 2 diabetes. Research suggests that moderate alcohol intake may decrease serum insulin levels, increase adiponectin (an adipocyte hormone inversely associated with type 2 diabetes) levels (25), and improve insulin sensitivity (76-79). On the other hand, heavy alcohol consumption may increase the risk of type 2 diabetes by contributing to obesity, especially abdominal obesity, disturbing carbohydrate metabolism, and/or impairing pancreatic or liver function (80).

Osteoporosis

Osteoporosis, a condition common among the elderly, results from progressive loss of bone mineral density (BMD). Several observational studies have associated light or moderate alcohol consumption with higher BMD in older adults compared to abstainers (81-91). Some studies have found stronger protective relationships among wine (89) or beer drinkers (89, 90) in comparison to those who consume liquor, suggesting that non-alcohol components (e.g., silicon in beer) might help explain the association. The effects of alcohol on bone health may also be dependent on age, gender, and hormonal status (reviewed in 92).

It is important to note that the available data come from observational studies, and the observed associations may be confounded, e.g., individuals who consume alcohol in moderation may have an overall healthier lifestyle than those who drink heavily or abstain. However, a recent study in perimenopausal women found that moderate alcohol intake was associated with improved BMD independent of various lifestyle factors, including smoking status, fruit and vegetable intake, and physical activity level (90).

Cognitive decline, dementia, and Alzheimer's disease

Although alcoholism and heavy alcohol consumption (>3-4 drinks/day) is known to increase the risk of cognitive impairment and dementia (93-95), recent meta-analyses and reviews have reported that light-to-moderate alcohol consumption in older adults is associated with a decreased risk of dementia and Alzheimer's disease when compared to abstention (93, 96, 97). Some meta-analyses have not found a significant reduced risk for vascular type dementia (96, 98) or for cognitive decline (93, 96, 98, 99). A few studies have suggested that consumption of wine may be especially protective against dementia, although inconsistent findings have been observed, and many studies have not distinguished among the various types of alcohol.

At least three epidemiological studies have used magnetic resonance imaging (MRI) to examine relationships between alcohol intake and subclinical abnormalities in the brains of healthy middle-aged or older adults. Two studies found that infarctions (areas of dead tissue) were less frequent in the brains of those reporting light or moderate alcohol intake compared to those who abstained from alcohol (100, 101). However, another study found no relationship between alcohol intake and the presence of infarction (102). Two of the studies measuring brain atrophy, a characteristic of Alzheimer's disease and alcoholic dementia, found brain atrophy to be lower in those who abstained from alcohol compared to alcohol consumers (100, 102). The other study found less brain atrophy with light-to-moderate alcohol consumption but only in carriers of the apolipoprotein E (APOE) ε4 allele, who are at increased risk for Alzheimer's disease (101). Because of the complex nature of alcohol's effects on the brain, further research is needed to determine the risks and benefits of alcohol consumption with respect to cognitive function and dementia.

Gallstones

The majority of prospective cohort studies (103-107) and case-control studies (108, 109) have found that men and women with moderate alcohol intakes have lower risks of gallstones or gallbladder surgery (cholecystectomy) than those who do not consume alcohol. Although the reasons for the consistent inverse association between moderate alcohol consumption and gallstone incidence are not entirely clear, regular alcohol intake may result in bile that is less likely to crystallize into gallstones or stimulate gallbladder emptying (106).

Health Risks of Moderate Alcohol Consumption

Pregnancy

Fetal alcohol spectrum disorders (FASD) is a continuum of developmental abnormalities resulting from gestational alcohol exposure; FASD may affect as many as 1%-2% of US children (110, 111). Fetal alcohol syndrome (FAS) — a severe FASD — is a cluster of physical and mental birth defects associated with heavy alcohol consumption during pregnancy. Some characteristics of FAS include facial abnormalities, mental retardation, and growth impairment. More moderate alcohol consumption during pregnancy (7-14 drinks/week) has been associated with more subtle effects on cognitive and behavioral development (112, 113). Children of mothers who drank moderately during pregnancy have been found to have problems with memory, attention and learning, and behavior (114). Overall, studies on the association of low-to-moderate drinking during pregnancy and mental health of offspring have reported mixed results (reviewed in 115). However, it is important to note that these studies are observational in nature and may have not adequately controlled for potential confounding factors (e.g., lifestyle differences [in women who drank alcohol during pregnancy versus those who abstained] that influence mental development) (115).

Since no safe level of alcohol consumption has been established at any stage of pregnancy, pregnant women and women who are planning a pregnancy should abstain from alcohol (116, 117).

Breast cancer

More than 100 observational studies have been completed on the association between alcohol consumption and female breast cancer, with most finding an increased risk (118-121). Even though the available data come from observational studies, many consider the association to be causal. Regular alcohol consumption as low as one or two drinks per day has been associated with modest but significant increases in breast cancer risk. A threshold for harm, however, is difficult to define due to potential underreporting of alcohol intake by heavy drinkers, which could result in heavy drinkers being misclassified as 'moderate alcohol consumers' (122).

A linear dose-dependent relationship between alcohol consumption and breast cancer risk has been observed for premenopausal and postmenopausal breast cancer regardless of the type of alcoholic beverage consumed. Pooled and meta-analyses have found that each 10-gram increase in daily alcohol consumption (slightly less than one drink) is associated with a 7%-10% increased risk of breast cancer in women (123-125). Studies of alcohol consumption and breast cancer-specific mortality have reported mixed results, with a recent meta-analysis of 25 prospective cohort studies finding an increased risk only with alcohol consumption in excess of 20 grams (1.4 drinks)/day (126). Moderate alcohol consumption has been consistently associated with reduced risk of all-cause mortality (see Mortality above).

Although the mechanisms for the consistent association between alcohol intake and breast cancer incidence have not been clearly identified, proposed mechanisms include acetaldehyde formation, induction of CYP2E1 metabolism and increased oxidative stress, increased circulating estrogen or androgen levels, and enhanced invasiveness of breast cancer cells (119, 127). Current estimates are that about one in eight women (12.4%) in the US will develop breast cancer at some point in her lifetime (128). Although there are many risk factors for breast cancer, alcohol consumption is one of only a few modifiable risk factors.

Folate and breast cancer

Alcohol interferes with the absorption, transport, and metabolism of folate, which is required for DNA methylation and DNA repair (see the article on Folate). Alterations in these processes may result in mutations or altered gene expression, which increase the risk of cancer (118). Several (129-134), but not all (135-139), studies have found that sufficient folate intake may modify the association between alcohol intake and breast cancer risk. Although the interactions between folate, alcohol, and breast cancer risk remain to be clarified, it makes sense for women who drink alcohol to take a daily multivitamin containing 400 μg of folic acid.

Progression to heavy or hazardous drinking

Some people, such as recovering alcoholics and those with family histories of alcohol abuse or alcoholism, may not be able to maintain moderate drinking habits. Susceptibility to alcoholism is affected by genetic, psychosocial, and environmental factors. Children of an alcoholic parent have been found to be at significantly higher risk of developing alcoholism than those without an alcoholic parent (140). This increase in risk is likely related to interactions between genetic factors and factors related to the family environment. The National Institute on Alcohol Abuse and Alcoholism recommends that people with a family history of alcoholism, especially in a parent, approach moderate drinking carefully (141).

Medication interactions

In the liver, alcohol is metabolized by the same enzymes as many medications. Therefore, alcohol consumption can affect the activation or breakdown of a number of medications. The consumption of alcohol may also increase sedation, drowsiness, and hypotensive effects caused by numerous prescription and over-the-counter medications. Although serious interactions between alcohol and medications are more common in the presence of heavy alcohol consumption, even moderate alcohol consumption may hypothetically increase the risk of some adverse reactions in susceptible people (142). Women and older adults are particularly at risk for interactions between alcohol and medications (143, 144).

Many different classes of prescription medication may interact adversely with alcohol, including antibiotics, anticonvulsants, anticoagulants (e.g., Coumadin), antidepressants, antidiabetic agents, antihypertensive agents, vasodilators (e.g., nitrates and calcium channel blockers), barbiturates, benzodiazepines (sedatives), histamine H_2-receptor blockers, muscle relaxants, and narcotic and non-narcotic pain relievers. Over-the-counter medications and herbal preparations may also interact with alcohol, including pain medications like aspirin, acetaminophen (Tylenol), ibuprofen (Advil, Motrin), and naproxen sodium (Aleve); cold and allergy medications like diphenhydramine (Benadryl) and chlorpheniramine; heartburn medications like cimetidine (Tagamet) and ranitidine (Zantac); and herbal preparations like chamomile, valerian, and kava.

To help avoid potentially serious interactions between alcohol and medications, make sure your health care provider is aware of your alcohol intake. Before taking prescription or over-the-counter medications, read the product warning labels or consult a pharmacist or health care provider to determine whether alcohol consumption increases the risk of adverse effects. It may, in general, be advisable to separate taking any medication and drinking alcohol by two to three hours. For more information on potentially serious interactions between alcohol and medications, see the National Institute on Alcohol Abuse and Alcoholism website.

Health Benefits of Heavy Alcohol Consumption

None

Health Risks of Heavy Alcohol Consumption

Pregnancy

Heavy consumption of alcohol during pregnancy causes fetal alcohol syndrome (FAS). See above.

Cardiovascular disease

Hypertension

Heavy alcohol consumption has been consistently associated with an increased risk of high blood pressure (hypertension) in prospective cohort and case-control studies (145-147). A 2009 systematic review and meta-analysis of 12 prospective cohort studies found consuming 50 grams (3.6 drinks)/day of alcohol was associated with a 1.6-fold and 1.8-fold higher risk of hypertension in men and women, respectively; alcohol intake at twice that level (100 grams (~7 drinks)/day) was associated with a relative risk of 2.5 for men and 2.8 for women (148).

The results of numerous clinical trials indicate that reducing alcohol intake lowers blood pressure in hypertensive and normotensive individuals. A meta-analysis that combined the results of 15 randomized controlled trials found that reducing alcohol consumption resulted in significant decreases in both systolic and diastolic blood pressure (149).

Stroke

Ischemic strokes are the result of insufficient blood flow to an area of the brain, which may occur when an artery supplying the brain becomes blocked by a blood clot. Hemorrhagic strokes occur when a blood vessel ruptures and bleeds into the brain. Although regular, moderate alcohol consumption has been associated with decreased risk of ischemic stroke in some studies, heavy alcohol consumption has been associated with increased risk of both ischemic stroke and hemorrhagic stroke. A meta-analysis that combined the results of 19 prospective cohort and 16 case-control studies found that heavy drinking more than doubled the risk of hemorrhagic stroke and increased the risk of ischemic stroke by 70% (59). A meta-analysis of recent studies (1980-2009) confirmed that heavy drinking is associated with increased risks of ischemic and hemorrhagic stroke in both men and women (60). Heavy alcohol consumption may increase the risk of stroke by contributing to hypertension, cardiomyopathy (heart muscle damage), cardiac rhythm disturbances, and coagulation (clotting) disorders and impaired hemostasis.

Cardiac arrhythmias and sudden cardiac death

The long-recognized association between bouts of heavy alcohol consumption and cardiac rhythm disturbances (arrhythmias) was called "holiday heart syndrome" because it was first described in people who were admitted to hospitals after holidays or weekends (150). Atrial fibrillation is the cardiac arrhythmia most commonly associated with heavy alcohol use (151, 152). A 2010 systematic review and meta-analysis found a dose-dependent association between daily alcohol consumption and risk of this type of cardiac arrhythmia, with an increased risk being found with consumption greater than 24 grams/day (1.7 drinks/day) for women and 36 grams/day (2.6 drinks/day) for men (153). A 2014 meta-analysis of seven prospective studies found that consumption of more than two drinks per day was associated with increased risk of atrial fibrillation in men and women, and the risk increased by 8% with each additional daily drink (154, 155). Additionally, several studies have found that heavy alcohol consumption (>5 drinks per day) increases risk of sudden cardiac death (SCD) (156, 157).

The ways by which alcohol may trigger arrhythmias and SCD are not fully known. Alcohol may interfere with the contractility of heart muscle cells, change the shape and structure of heart muscle cells, contribute to electrolyte imbalance, and/or induce oxidative stress (158).

Alcoholic cardiomyopathy

Alcoholic cardiomyopathy is a heart muscle disease caused by long-term, heavy alcohol consumption (159); this disease likely occurs in only a small proportion (<10%) of heavy drinkers (160). Alcoholic cardiomyopathy occurs in two stages: (1) an early asymptomatic stage, when the damage to the heart muscle has no obvious symptoms; and (2) a symptomatic stage, when the heart muscle is too weak to pump effectively. Although the level of alcohol consumption resulting in alcoholic cardiomyopathy has not been clearly established, people consuming at least seven alcoholic drinks daily for more than five years are thought to be at risk of developing asymptomatic alcoholic cardiomyopathy. Those who continue to drink heavily ultimately develop heart failure. Research suggests that women may be more susceptible to alcohol's toxic effects on the heart muscle than men (161, 162).

Alcoholic liver disease

Chronic excessive alcohol use is a major cause of illness and death from liver disease (163). Alcoholic liver disease is characterized by a spectrum of liver injury, including steatosis (fatty liver), hepatitis (a potentially fatal inflammation of the liver), fibrosis, and cirrhosis — the most advanced form of alcoholic liver disease. In cirrhosis, the formation of fibrotic scar tissue results in progressive deterioration of liver function. Complications of advanced liver disease include severe bleeding from distended veins in the esophagus (esophageal varices), brain damage (hepatic encephalopathy), fluid accumulation in the abdomen (ascites), and kidney failure.

A 2004 meta-analysis of nine studies found a dose-responsive increase in risk for liver cirrhosis with increasing amounts of alcohol consumed: relative risks (RR) of 2.9 for 25 grams (1.8 drinks)/day, 7.1 for 50 grams (3.6 drinks)/day, 26.5 for 100 grams (7.1 drinks)/day (164). Another meta-analysis found a higher RR for liver cirrhosis with increasing doses but also suggested a threshold response for morbidity from liver cirrhosis (higher risk in women with consumption >24 g (1.7 drinks)/day of alcohol, and higher risk in men with consumption >36 g (2.6 drinks)/day of alcohol) (165). Risk of mortality from liver cirrhosis was increased with any alcohol consumption in women and with consumption of >12 g (0.9 drinks)/day in men; a stronger relationship between alcohol consumption and mortality from liver cirrhosis versus morbidity might be expected because alcohol consumption is known to exacerbate any existing liver disease (165).

Serious liver disease has been found to develop in approximately 10% of those who consume more than 60 grams per day of alcohol (4.3 drinks/day). Women are more susceptible to serious alcoholic liver disease than men (165, 166), and individuals with hepatitis C infection have an increased risk of alcoholic liver disease (167).

Cancer

Heavy alcohol consumption has been found to increase the risk of cancer at a number of sites (168). Heavy alcohol consumption is consistently and dose-dependently associated with increases in risk of cancers of the mouth, pharynx, larynx, esophagus, liver, colon, rectum, and breast (165). Moreover, the combination of smoking and alcohol results in even more dramatic increases in cancer risks (169). Increased risk of liver cancer with long-term heavy alcohol consumption may be related to alcoholic cirrhosis of the liver or increased susceptibility to cancer caused by viral hepatitis.

Alcohol-related brain disorders

Chronic heavy alcohol use and alcohol dependence are associated with detrimental effects on the brain and its function, especially memory and executive functions (170). Alcoholics have been observed to suffer from cerebral atrophy (shrinkage of brain tissue), which likely contributes to alcohol-associated dementia and cognitive impairment (94). In contrast to the progressive cerebral atrophy observed in Alzheimer's disease, alcohol-related cerebral atrophy may decrease after a period of abstinence. Alcohol-related brain disorders may be associated with nutritional deficiencies like thiamin (171) or niacin (172).

Pancreatitis

Pancreatitis is a painful inflammation of the pancreas. Acute pancreatitis is characterized by the sudden onset of severe upper abdominal pain, often accompanied by nausea and vomiting (173). Although most attacks of acute pancreatitis require only supportive care, a small percentage of people may experience serious or life-threatening complications. Studies estimate that 19%-32% of acute pancreatitis cases have an alcoholic etiology (reviewed in 174).

Chronic pancreatitis results in progressive destruction of the pancreas, leading to loss of pancreatic function (175). An estimated 60%-72% of chronic pancreatitis cases have an alcoholic etiology. The risk of developing chronic pancreatitis increases with the quantity and duration of alcohol consumed: an increased risk of chronic pancreatitis is observed with long-term consumption of five or more alcoholic drinks per day (174). Only a small percentage (<10%) of alcoholics develop clinical pancreatitis; thus, hereditary and environmental factors are also thought to play a role. The disease is more common in men than in women, in Blacks compared to Whites, and in smokers versus nonsmokers (176, 177).

Bone health

Chronic alcoholism has deleterious effects on bone health, including decreased bone mineral density and increased risk of fracture. Consumption of large quantities of alcohol (100-200 grams/day) directly impairs activity of osteoblasts — the bone-forming cells. Negative effects on bone health are also indirectly caused by the malnutrition experienced by alcoholics (92).

Accidents, injury, and violence

Alcohol use is associated with an increased risk of injury in a number of circumstances, including motor vehicle accidents, falls, and fires (178). Data from hospital emergency departments indicate that consuming as little as one or two alcoholic drinks in the previous six hours significantly increases the risk of injury (179). Thirty-one percent of all traffic fatalities in the US are alcohol-related (180). Although the legal blood alcohol concentration (BAC) limit for drivers is 0.08 (grams of alcohol/deciliter of blood) in the US, most scientific studies have found significant impairment of driving-related skills at a BAC of 0.05 (181). For reference, a BAC of 0.05 might be achieved by a 175-pound male consuming three standard alcoholic drinks in one hour or a 120-pound female consuming two drinks in one hour (182).

Excessive alcohol use is associated with all forms of violence, including suicide, homicide, domestic violence, sexual assault, and gang violence. Although the reasons for alcohol-associated violence are complex, alcohol use appears to increase the risk of violent behavior in some populations (183).

Mortality

Heavy alcohol consumption increases the risk of mortality (4, 16). As mentioned above, the relationship between alcohol consumption and mortality is often described as J-shaped, meaning those with high intakes of alcohol have a higher risk of mortality than nondrinkers. A 2011 meta-analysis of eight prospective cohort studies found that consumption of >60 grams/day of alcohol was associated with a 30% increase in mortality from all causes (16).

  - Flavonoids
  - Peptides

Life Stages

Nutritional needs change throughout the life cycle. Growth and development during infancy, childhood, and adolescence require special intakes of many micronutrients. Nutritional needs also change throughout the stages of adulthood. For example, micronutrient requirements during pregnancy and lactation are increased, and micronutrient needs of older adults reflect age-related changes in nutrient absorption and metabolism.

This section of the site is under development; new articles will be added in the future.

Micronutrient Requirements of Children Ages 4 to 13 Years

Introduction

The period of childhood between ages 4 and 13 years is characterized by continued physical growth and rapid cognitive, emotional, and social development (1, 2). Many children, especially girls, undergo their pubertal growth spurt between ages 4 and 13. This period of childhood precedes adolescence — the transitional stage of development between childhood and adulthood. Due to increased growth and metabolism, the nutritional requirements of children are higher in proportion to body weight compared with adults (1, 3). Good nutrition throughout childhood is important not only to support normal growth and cognitive development but also to establish healthy eating patterns that are associated with decreased risk of chronic conditions and diseases in adulthood, including obesity, type 2 diabetes, cardiovascular disease, metabolic syndrome, and osteoporosis.

Inadequate intake of nutrients can impair growth and development in children. This article discusses micronutrient (vitamins and nutritionally essential minerals) requirements of children ages 4 to 13 years. The Food and Nutrition Board (FNB) of the Institute of Medicine establishes dietary reference intakes (DRIs) for each micronutrient; these reference values should be used to plan and assess dietary intakes in healthy people (4, 5). The DRIs include the estimated average requirement (EAR), the recommended dietary allowance (RDA), the adequate intake (AI), and the tolerable upper intake level (UL). The RDA, which is the average daily dietary intake level of a nutrient sufficient to meet the requirements of almost all (97.5%) healthy individuals in a specific life stage and gender group, should be used in the planning of diets for individuals (6). An AI recommendation is set when an RDA cannot be determined. In children, these intake recommendations are based on data regarding average micronutrient intakes of children and also on certain criteria for micronutrient adequacy. However, because of limited data, many of the micronutrient intake recommendations for children are extrapolated from recommendations for adults using a formula that accounts for metabolic body weight and growth (3). Metabolic body weight is determined by calculating the 0.75 power of body mass (body mass^0.75) (7). To account for growth, the equation used to derive an RDA or AI involves an age group-specific growth factor (3). The FNB establishes separate dietary intake recommendations for children between the ages of 4 to 8 years and those between the ages of 9 and 13 years (see Ages 4 to 8 Years and Ages 9 to 13 Years).

Micronutrient Needs of Children Ages 4 to 8 Years

For each micronutrient, the FNB sets an RDA or AI for children ages 4 to 8 years; these micronutrient intake recommendations do not differ with gender for this age group. **Table 1** lists the RDA for each micronutrient. As mentioned above, the RDA should be used in the planning of diets for individuals. A few select micronutrient requirements for children are discussed below.

Table 1. Dietary Reference Intakes Set by the FNB:
RDA for Micronutrients During Childhood, Ages 4 to 8 Years

Micronutrient	Males and Females
Biotin	12 μg/day (AI)
Folate	200 μg/day^a
Niacin	8 mg/day^b
Pantothenic Acid	3 mg/day (AI)
Riboflavin	600 μg/day
Thiamin	600 μg/day
Vitamin A	400 μg/day (1,333 IU/day)^c
Vitamin B$_6$	600 μg/day
Vitamin B$_{12}$	1.2 μg/day
Vitamin C	25 mg/day
Vitamin D	15 μg/day (600 IU/day)
Vitamin E	7 mg/day (10.5 IU/day)^d
Vitamin K	55 μg/day (AI)
Calcium	1,000 mg/day
Chromium	15 μg/day (AI)
Copper	440 μg/day
Fluoride	1 mg/day (AI)
Iodine	90 μg/day
Iron	10 mg/day
Magnesium	130 mg/day
Manganese	1.5 mg/day (AI)
Molybdenum	22 μg/day
Phosphorus	500 mg/day
Potassium	2,300 mg/day (AI)
Selenium	30 μg/day
Sodium	1,000 mg/day (AI)
Zinc	5 mg/day
Choline^e	250 mg/day (AI)
α-Linolenic Acid^e	900 mg/day (AI)
Linoleic Acid^e	10 g/day (AI)

AI, adequate intake
^{a}Dietary Folate Equivalents
^{b}NE, niacin equivalent: 1 mg NE = 60 mg tryptophan = 1 mg niacin
^{c}Retinol Activity Equivalents
^{d}α-Tocopherol
^{e}Considered an essential nutrient, although not strictly a micronutrient

Micronutrient Needs of Children Ages 9 to 13 Years

For each micronutrient, the FNB sets an RDA or AI for children ages 9 to 13 years; these recommendations are gender specific to account for the unique nutritional needs of boys and girls as they undergo puberty. **Table 2** lists the RDA for each micronutrient by gender. The RDA should be used in the planning of diets for individuals. A more detailed discussion of the requirements of certain micronutrients for children can be found below.

Table 2. Dietary Reference Intakes Set by the FNB:
RDA for Micronutrients During Childhood, Ages 9 to 13 Years

Micronutrient	Males	Females
Biotin	20 μg/day (AI)	20 μg/day (AI)
Folate	300 μg/day^a	300 μg/day^a
Niacin	12 mg/day^b	12 mg/day^b
Pantothenic Acid	4 mg/day (AI)	4 mg/day (AI)
Riboflavin	900 μg/day	900 μg/day
Thiamin	900 μg/day	900 μg/day
Vitamin A	600 μg/day (2,000 IU/day)^c	600 μg/day (2,000 IU/day)^c
Vitamin B$_6$	1 mg/day	1 mg/day
Vitamin B$_{12}$	1.8 μg/day	1.8 μg/day
Vitamin C	45 mg/day	45 mg/day
Vitamin D	15 μg/day (600 IU/day)	15 μg/day (600 IU/day)
Vitamin E	11 mg/day (16.5 IU/day)^d	11 mg/day (16.5 IU/day)^d
Vitamin K	60 μg/day (AI)	60 μg/day (AI)
Calcium	1,300 mg/day	1,300 mg/day
Chromium	25 μg/day (AI)	21 μg/day (AI)
Copper	700 μg/day	700 μg/day
Fluoride	2 mg/day (AI)	2 mg/day (AI)
Iodine	120 μg/day	120 μg/day
Iron	8 mg/day	8 mg/day
Magnesium	240 mg/day	240 mg/day
Manganese	1.9 mg/day (AI)	1.6 mg/day (AI)
Molybdenum	34 μg/day	34 μg/day
Phosphorus	1,250 mg/day	1,250 mg/day
Potassium	2,500 mg/day (AI)	2,300 mg/day (AI)
Selenium	40 μg/day	40 μg/day
Sodium	1,200 mg/day (AI)	1,200 mg/day (AI)
Zinc	8 mg/day	8 mg/day
Choline^e	375 mg/day (AI)	375 mg/day (AI)
α-Linolenic Acid^e	1,200 mg/day (AI)	1,000 mg/day (AI)
Linoleic Acid^e	12 g/day (AI)	10 g/day (AI)

AI, adequate intake
^{a}Dietary Folate Equivalents
^{b}NE, niacin equivalent: 1 mg NE = 60 mg tryptophan = 1 mg niacin
^{c}Retinol Activity Equivalents
^{d}α-Tocopherol
^{e}Considered an essential nutrient, although not strictly a micronutrient

Vitamins

Vitamin A

Vitamin A is a fat-soluble vitamin that is essential for growth and development, normal vision, the expression of selected genes, and immunity (see the article on Vitamin A). Vitamin A deficiency is a major public health problem worldwide. It is the leading preventable cause of blindness among children in developing nations (8). The earliest evidence of vitamin A deficiency is impaired dark adaptation or night blindness. Mild vitamin A deficiency may result in Bitot's spots, which are changes in the conjunctiva (the mucous membrane that lines the eyelids and the outer surface of the eye). Severe or prolonged vitamin A deficiency causes a condition called xerophthalmia (dry eye), characterized by changes in the cells of the cornea (clear covering of the eye) that ultimately result in corneal ulcers, scarring, and blindness (9, 10).

Vitamin A deficiency also places children at a heightened risk for infectious disease; in fact, vitamin A deficiency can be considered a nutritionally acquired immunodeficiency disorder (11). Even children who are only mildly deficient in vitamin A have a higher incidence of respiratory disease and diarrhea, as well as a higher rate of mortality from infectious disease, compared to children who consume sufficient vitamin A (12). Vitamin A supplementation in children has been found to decrease both the severity and incidence of deaths related to diarrhea and measles in developing countries, where vitamin A deficiency is common (13). The onset of infection reduces blood retinol (preformed vitamin A) levels very rapidly. This phenomenon is generally believed to be related to decreased synthesis of retinol binding protein (RBP) by the liver. In this manner, infection stimulates a vicious cycle, because inadequate vitamin A nutritional status is related to increased severity and likelihood of death from infectious disease (14).

The RDA for vitamin A is based on the amount needed to ensure adequate stores (four months) of vitamin A in the body to support normal reproductive function, immune function, vitamin A-dependent gene expression, and vision (15). Vitamin A intake recommendations for children were derived by extrapolating the recommendation for adults using metabolic body weight, accounting for growth. The RDA for children ages 4 to 8 years is 400 μg/day of Retinol Activity Equivalents (RAE), which is 1,333 international units (IU); the RDA for both boys and girls ages 9 to 13 years is 600 μg/day of RAE, which is equivalent to 2,000 IU. For information on vitamin A content in foods, see the article on Vitamin A.

Vitamin B$_{12}$

Vitamin B$_{12}$ is needed for two sorts of reactions in the human body. One is transmethylation (methyl transfer between two molecules) that leads to the synthesis of the amino acid methionine from homocysteine. Methionine, in turn, is required for the synthesis of S-adenosylmethionine, a methyl group donor used in many biological methylation reactions, such as the methylation of sites within DNA and RNA (16). The second sort of reaction is isomerization (rearrangement of a molecule). Vitamin B$_{12}$ acts as a coenzyme for methylmalonyl-CoA mutase to convert methylmalonyl-CoA to succinyl-CoA, an important step for the metabolism of proteins and lipids. Both transmethylation and isomerization reactions are essential for the metabolism of components of the myelin sheath of nerve cells and for the metabolism of neurotransmitters. Accordingly, vitamin B$_{12}$ deficiency damages the myelin sheath covering cranial, spinal, and peripheral nerves, resulting in neurological damage (17, 18). The myelin sheath is the insulating layer of tissue made up of lipids and proteins that surrounds nerve fibers. This sheath acts as a conduit in an electrical system, allowing rapid and efficient transmission of nerve impulses (19). In some cases, neurologic symptoms caused by vitamin B$_{12}$ deficiency can be reversed by vitamin treatment (18), but reversibility seems to be dependent upon the duration of the associated neurologic complications (20).

Although myelination primarily occurs during fetal development and early infancy, it continues through childhood, adolescence, and stages of early adulthood (21, 22). Because of the role of vitamin B$_{12}$ in myelination and other metabolic processes, it is important for children to meet dietary intake recommendations. The RDA of vitamin B$_{12}$ for children ages 4 to 8 years is 1.2 μg/day, and the RDA for boys and girls ages 9 to 13 years is 1.8 μg/day. This vitamin is naturally present only in animal products, such as meat, poultry, fish (including shellfish), and to a lesser extent in milk, but it is not generally present in plant products or yeast (9). Thus, children who have vegan diets need supplemental vitamin B$_{12}$ or need adequate intake from fortified foods.

Vitamin C

Vitamin C has a number of important roles during growth and development, including being required for the synthesis of collagen, carnitine, and neurotransmitters (23). Vitamin C is also a highly effective antioxidant and is important for immunity (see the article on Immunity). Further, vitamin C strongly enhances the absorption of non heme iron by reducing dietary ferric iron (Fe^{3+}) to ferrous iron (Fe^{2+}) and forming an absorbable, iron-ascorbic acid complex. Specifically, iron absorption is 2- to 3-fold higher with co-ingestion of 25 to 75 mg of vitamin C (24). This has special relevance to child health, considering the fact that iron deficiency is the most common nutrient deficiency in the world (see Iron below). Vitamin C intake recommendations for children are extrapolated from recommendations for adults based on relative body weight. The RDA for children ages 4 to 8 years is 25 mg/day, and the RDA for boys and girls ages 9 to 13 years is 45 mg/day (25). For information on food sources, see the article on Vitamin C.

Vitamin D

Vitamin D is a fat-soluble vitamin that is essential for maintaining normal calcium metabolism and is thus necessary for bone health. Severe vitamin D deficiency in infants and children results in the failure of bone to mineralize, leading to a condition known as rickets. Rapidly growing bones are most severely affected by rickets. The growth plates of bones continue to enlarge, but in the absence of adequate mineralization, weight-bearing limbs (arms and legs) become bowed. In severe cases of vitamin D deficiency, low serum calcium levels (hypocalcemia) may induce seizures. Although fortification of foods has led to complacency regarding vitamin D deficiency, nutritional rickets is still being reported in the United States and other nations (26-33).

In the US, fortified foods are a major contributor to dietary vitamin D intake, especially in children, because only a few foods naturally contain vitamin D (see the article on Vitamin D). In the US, milk is voluntarily fortified with 400 IU (10 μg) of vitamin D per quart (946 mL) (34), and other foods may be fortified with varying concentrations of vitamin D. According to a recent report regarding the American food supply, nearly all milk, about 75% of ready-to-eat breakfast cereals, around 50% of milk substitutes, about 25% of yogurts, and 8-14% of juices, cheeses, and spreads are fortified with vitamin D (35). Although not required by the US FDA to be listed on the Nutrition Facts food label, some packaged foods, particularly cereals, include the amount of vitamin D in one serving as the percentage of the Daily Value (DV). The DV is 400 IU, but the RDA for children ages 4 to 8 years and for boys and girls ages 9 to 13 years is 600 IU/day. In Canada, vitamin D fortification of milk and margarine is mandatory, with milk containing 35-45 IU per 100 mL (331-426 IU per quart) and margarine containing 530 IU per 100 grams (34), but vitamin D fortification of foods is less common in European nations (36). In addition to diet, vitamin D can be endogenously synthesized in the skin upon exposure to ultraviolet-B radiation from sunlight; however, sunscreens effectively block synthesis of vitamin D in skin (see the article on Vitamin D).

When setting the RDA for vitamin D, the FNB assumed minimal sun exposure, even though sun exposure could provide most people with their entire vitamin D requirement. For US children to meet the RDA of 600 IU/day (15 μg/day), about 6 cups of milk would need to be consumed each day. Analysis of data from the National Health and Nutrition Examination Survey (NHANES) 2005-2006 found that average total vitamin D intakes (from diet and supplements combined) in US children of ages 4 to 8 were 9.3 μg/day (372 IU/day) for boys and 7.9 μg/day (316 IU/day) for girls (37). Even though the analysis found that 43% of boys and 34% of girls in this age group took supplements containing vitamin D (37), their average total daily intakes were well below the current RDA of 600 IU/day (15 μg/day). Total daily vitamin D intakes were even lower for chilren aged 9 to 13 years (boys, 7.5 μg or 300 IU/day; girls, 7.7 μg or 308 IU/day). Sun exposure can substantially affect body vitamin D levels, and measuring 25-hydroxyvitamin D — the major circulating form of vitamin D — is a useful indicator of vitamin D status. It is assumed that a dietary intake of 600 IU/day results in a serum 25-hydroxyvitamin D level of 50 nmol/L (20 ng/mL), which the FNB considers as the cut-point for vitamin D adequacy (38). However, higher serum 25-hydroxyvitamin D serum levels may benefit health; thus, the Linus Pauling Institute recommends that children ages 4 to 13 years should have a daily intake of 600 to 1,000 IU (15 to 25 μg) of vitamin D, consistent with the recommendations of the Endocrine Society (39). Given the average vitamin D content of the diets of children, supplementation may be necessary to meet these recommendations. The American Academy of Pediatrics currently suggests that all children receive 400 IU of supplemental vitamin D daily (26) — an amount that is typically found in multivitamin supplements.

The tolerable upper intake level (UL) — the highest level of daily intake of a specific nutrient likely to pose no risk of adverse health effects in almost all individuals — for children ages 4 to 8 years is 3,000 IU/day (75 μg/day) of vitamin D; the UL for boys and girls ages 9 to 13 years is 4,000 IU (100 μg/day).

Vitamin E

The RDA for vitamin E in children, expressed as an amount of the α-tocopherol form of the vitamin, was based on extrapolations from intake recommendations for adults, accounting for differences in lean body mass and increased needs of growth during childhood. The RDA is 7 mg/day (10.5 IU/day) for children ages 4 to 8 years and 11 mg/day (16.5 IU/day) for boys and girls ages 9 to 13 years (40). A US national survey, NHANES 1999-2000, found that children ages 4 to 8 years had an average intake of 5.2 mg/day of α-tocopherol; this survey found that average α-tocopherol intakes for boys and girls ages 9 to 13 years were 6.0 mg/day and 5.3 mg/day, respectively (41). These intakes are below the current RDA. Surveys in The Republic of Korea and Germany have also reported low intakes of vitamin E in children (42, 43). However, true vitamin E deficiency is rare and has been observed only in cases of severe malnutrition, genetic defects affecting the α-tocopherol protein, and fat malabsorption syndromes; see the article on Vitamin E.

Minerals

Calcium

About 99% of calcium in the body is found in bones and teeth (44). Adequate intake of calcium throughout childhood and adolescence is important for proper mineralization of growing bones, attainment of peak bone mass, and reduction of risk for osteoporosis in adulthood (38). Thus, dietary intake recommendations for calcium in children are established based on the calcium intake needed to support bone accretion and overall calcium retention (i.e., the dietary intake needed to achieve positive calcium balance) (38). The RDA is 1,000 mg/day for children ages 4 to 8 years and 1,300 mg/day for boys and girls ages 9 to 13 years. Calcium intake recommendations are higher in children ages 9 to 13 to account for increased needs of the mineral during puberty (38).

Many American children have dietary calcium intakes below current recommendations, with girls having lower intakes than boys. A recent study reported daily calcium intake in children using data from NHANES 2003-2006, a US national survey (37). An estimated 17% of boys and 33% of girls between the ages of 4 and 8 have total calcium intakes (dietary plus supplemental intakes) of 800 mg/day or less. For children in this age group, average intake from supplements in those who took supplemental calcium (29% of boys; 26% of girls) was 99 mg/day and 87 mg/day for boys and girls, respectively. In children 9 to 13 years old, only 23% of boys and 15% of girls met the RDA for calcium, even though 20% of boys and 24% of girls took supplemental calcium (average supplemental calcium intake of 104 mg/day for boys and 80 mg/day for girls) (37). Dairy products, which provide about 72% of the calcium in the American diet (44), represent rich and absorbable sources of calcium. Milk contains 300 mg of calcium per cup; therefore, children ages 4 to 8 and children ages 9 to 13 could meet the RDA for calcium by drinking 3.3 or 4.3 cups of milk daily, respectively. Certain vegetables and grains also provide calcium, but their bioavailability is lower compared with dairy. For more information on dietary sources of calcium and calcium bioavailability, see the article on Calcium. If children do not meet the RDA through diet alone, LPI recommends supplemental calcium. Children's multivitamin/mineral supplements generally provide no more than 150 mg of calcium.

The Nutrition Facts label of packaged foods lists calcium content in one serving as a percent of the Daily Value (DV), with the DV being 1,000 mg. Since the RDA for children ages 4 to 8 is 1,000 mg/day, the listed amount of calcium on the food label directly provides a percentage of the RDA. However, because the RDA for children ages 9 to 13 years is higher, the percentage of the DV listed would be an overestimation of the percentage of the RDA.

Fluoride

The mineral fluoride is important for the prevention of dental caries (tooth decay). Specific cariogenic (cavity-causing) bacteria found in dental plaque are capable of metabolizing certain carbohydrates (sugars) and converting them to organic acids that can dissolve tooth enamel. If unchecked, the bacteria may penetrate deeper layers of the tooth and progress into the soft pulp tissue at the center. Untreated caries can lead to severe pain, local infection, tooth loss or extraction, nutritional problems, and serious systemic infections in susceptible individuals (45). Increased fluoride exposure, most commonly through water fluoridation, has been found to decrease dental caries (46). Fluoride consumed in water appears to have a systemic effect in children before teeth erupt, as well as a topical (surface) effect in children and adults after teeth have erupted. The FNB set an adequate intake (AI) recommendation based on estimated intakes (0.5 mg/kg of body weight) that have been shown to reduce the occurrence of dental caries most effectively without causing the unwanted side effect of tooth enamel mottling, a white speckling or mottling of the permanent teeth known as dental fluorosis (47). The AI of fluoride for children ages 4 to 8 years is 1 mg/day, and the AI for boys and girls ages 9 to 13 years is 2 mg/day. For information about sources of fluoride, see the article on Fluoride.

Additionally, fluoridated toothpastes are very effective in preventing dental caries but add considerably to fluoride intake of children, especially young children who are more likely to swallow toothpaste. Researchers estimate that children under 6 years of age ingest an average of 0.3 mg of fluoride from toothpaste with each brushing, and swallowing fluoride-containing toothpaste is a major source of excess fluoride intake in this age group. Children who ingest more than two or three times the recommended fluoride intake are at increased risk of dental fluorosis. To prevent dental fluorosis while providing optimum protection from tooth decay, it is recommended that parents supervise children under 6 years of age while brushing with fluoridated toothpaste. In addition to discouraging the swallowing of toothpaste, children should be encouraged to use no more than a pea-size application of toothpaste and to rinse their mouths with water after brushing (47, 48). Fluoride supplements, available only by prescription, are intended for children living in areas with low water fluoride concentrations for the purpose of bringing their intake to approximately 1 mg/day (47). For more information about dental fluorosis, see the article on Fluoride.

Iodine

Iodine is required for the synthesis of the thyroid hormones, triiodothyronine (T$_3$) and thyroxine (T$_4$). To meet the body's demand for thyroid hormones, the thyroid gland traps iodine from the blood and incorporates it into thyroid hormones that are stored and released into the circulation when needed. In target tissues, such as the liver and the brain, T$_3$, the physiologically active thyroid hormone, can bind to thyroid receptors in the nuclei of cells and regulate gene expression. In target tissues, T$_4$, the most abundant circulating thyroid hormone, can be converted to T$_3$ by selenium-containing enzymes known as deiodinases. In this manner, thyroid hormones regulate a number of physiologic processes, including growth, development, metabolism, and reproductive function (49, 50).

Iodine deficiency is now accepted as the most common cause of preventable brain damage in the world. The spectrum of iodine deficiency disorders (IDD) includes mental retardation, hypothyroidism, goiter, and varying degrees of other growth and developmental abnormalities (49, 51). Iodine deficiency is associated with goiter; the incidence of goiter is higher in girls than boys. Children in iodine-deficient areas show poorer school performance, lower IQs, and a higher incidence of learning disabilities than matched groups from iodine-sufficient areas. A meta-analysis of 18 studies concluded that iodine deficiency alone lowered mean IQ scores in children by 13.5 points (52, 53).

Global estimates indicate that 31.5% of children between the ages of 6 and 12 years (266 million total children) has insufficient iodine intake (54). Major international efforts have produced dramatic improvements in the correction of iodine deficiency in the 1990s, mainly through the use of iodized salt in iodine-deficient countries (55). Today, 70% of households in the world use iodized salt (57), but iodine deficiency in children is still a major public health concern worldwide (57-59). For more information on the international effort to eradicate iodine deficiency, visit the websites of the International Council for the Control of Iodine Deficiency Disorders (ICCIDD) or the World Health Organization.

The RDA of iodine for children aged 4 to 8 years is 90 μg/day, and the RDA for boys and girls aged 9 to 13 years is 120 μg/day. The intake recommendation for children in this younger age group was based on results of a balance study in eight-year-old children who did not have goiters (60). Results of a balance study in children ages 9 to 13 years indicated that a minimum of 55 μg/day of iodine is needed (60), but the RDA for this older age group was set by extrapolating from the adult recommendation based on metabolic body weight (55). The amount of iodine in iodized salt and the contribution of iodized salt to total iodine intake vary by nation. In the US, iodized salt contains an average of 45 mg of iodine per kilogram and 20% of the salt consumed by Americans is iodized. Salt used in processed foods and the fast food industry is generally not iodized (61). However, the US is currently considered to be iodine-sufficient (62). Seafood is rich in iodine because marine animals can concentrate the iodine from seawater, and certain types of seaweed (e.g., wakame) are also very rich in iodine (see Table 3 in the article on Iodine). Dairy products are also relatively good sources of iodine. However, iodine content of plant foods depends on the iodine content of the soil (63).

Iron

Iron is an essential component of hundreds of proteins and enzymes involved in various aspects of metabolism, including oxygen transport and storage, electron transport and energy metabolism, antioxidant and beneficial pro-oxidant functions, oxygen sensing, and DNA synthesis (9, 64-68); see the article on Iron). Iron is stored in the body as ferritin, and serum level of ferritin is a good clinical indicator of iron status in children (69). Iron deficiency, which is the most common nutritional deficiency in the world, is a major public health problem, especially in developing nations, but it is also prevalent in industrialized nations. Severe iron deficiency leads to iron-deficiency anemia, which affects more than 30% of the global population (2 billion people) (70). Iron-deficiency anemia results when there is inadequate iron to support normal red blood cell formation. The anemia of iron deficiency is characterized as microcytic and hypochromic, meaning red blood cells are measurably smaller than normal and their hemoglobin content is decreased. At this most severe stage of iron deficiency, symptoms may be a result of inadequate oxygen delivery due to anemia and/or sub-optimal function of iron-dependent enzymes. Low red cell count, low hematocrit, and low hemoglobin concentrations are all used in the clinical diagnosis of iron-deficiency anemia (71). For details regarding the clinical diagnosis of iron-deficiency anemia, see Chapter 4 in the book, Nutritional Anemia, which is available through the Sight and Life website.

Most observational studies have found relationships between iron-deficiency anemia in children and poor cognitive development, poor school achievement, and behavior problems. However, it is difficult to separate the effects of iron-deficiency anemia from other types of deprivation in such studies, and confounding factors may contribute to the association between iron deficiency and cognitive deficits (72). Yet, several possible mechanisms link iron-deficiency anemia to altered cognition. For example, any cognitive benefit associated with iron supplementation could be possibly due to changes in nerve myelination, which have been observed in iron-deficient animals (73). Iron has an important role in the development of the cells that produce myelin (74); as noted above, the myelin sheath is the insulating layer of tissue comprised of lipids and proteins that surrounds nerve fibers. This sheath acts as a conduit in an electrical system, allowing for rapid and efficient transmission of nerve impulses (19). Iron is also important for enzymes involved in the synthesis of certain neurotransmitters and for DNA synthesis (75).

Children between the ages of 4 and 13 years are at lower risk of iron deficiency compared to younger or older children because infants, toddlers, and adolescents generally have higher growth rates (9). The RDA of iron for children ages 4 to 8 years is 10 mg/day, and the RDA for boys and girls ages 9 to 13 years is 8 mg/day. Girls in this latter age group who start to menstruate need an additional 2.5 mg/day of iron. These intake recommendations were based on a factorial modeling approach that accounts for the amount of iron needed to replace basal losses (losses in urine, feces, and sweat) and the iron requirements associated with growth (increases in hemoglobin, the oxygen-carrying pigment in red blood cells mass; increases in iron content of tissues; and for the younger age group, increases in iron storage). The intake recommendations also account for average bioavailability (the fraction of iron retained and used by the body) of dietary iron in these age groups (76).

The amount of bioavailable iron in food (or supplements) is influenced by the iron nutritional status of the individual and also by the form of iron (heme or nonheme). Individuals who are anemic or iron deficient absorb a larger percentage of the iron they consume (especially nonheme iron) than individuals who are not anemic and have sufficient iron stores (77, 78). In addition, heme iron, found in meat, poultry, and fish, is more readily absorbed and its absorption is less affected by other dietary factors than nonheme iron — the form found in plants, dairy products, fortified foods, and supplements. Although heme iron generally accounts for only 10-15% of the iron found in the diet, it may provide up to one third of total absorbed dietary iron (67, 77). The absorption of nonheme iron is strongly influenced by enhancers and inhibitors present in the same meal (77, 78). For instance, vitamin C strongly enhances the absorption of nonheme iron by reducing dietary ferric iron (Fe^{3+}) to ferrous iron (Fe^{2+}) and forming an absorbable, iron-ascorbic acid complex. Organic acids, such as citric, malic, tartaric, and lactic acids, also enhance nonheme iron absorption. Further, consumption of meat, poultry, and fish enhance nonheme iron absorption, but the mechanism for this increase in absorption is not clear (76, 77). Inhibitors of nonheme iron absorption include phytic acid, which is present in legumes, grains, and rice. In fact, small amounts of phytic acid (5 to 10 mg) can reduce nonheme iron absorption by 50%. The absorption of iron from legumes, such as soybeans, black beans, lentils, mung beans, and split peas, has been shown to be as low as 2% <a href=">(64, 76). Additionally, polyphenols found in some fruit, vegetables, coffee, tea, wines, and spices can markedly inhibit the absorption of nonheme iron, but this effect is reduced by the presence of vitamin C (64, 76). Soy protein, such as that found in tofu, has an inhibitory effect on iron absorption that is independent of its phytic acid content (76).

Magnesium

The mineral magnesium is involved in more than 300 essential metabolic reactions that are generally involved in energy production and the synthesis of nucleic acids (DNA and RNA), proteins, carbohydrates, and lipids (79). Magnesium also plays structural roles in bone, cell membranes, and chromosomes and is also required for various cellular processes, including ion transport across cell membranes, cell signaling, and cell migration (80).

The RDA of magnesium for children ages 4 to 8 years, which is 130 mg/day, was derived by extrapolating data from magnesium balance studies in older children (79). The RDA for boys and girls ages 9 to 13 years is 240 mg/day. This recommendation was based on data from magnesium balance studies in children of this age (81, 82). Good dietary sources of magnesium include nuts and green leafy vegetables because magnesium is part of chlorophyll — the green pigment in plants. Meats and milk have an intermediate magnesium content, with milk providing 24-39 mg per cup (79, 83). Refined foods generally have the lowest magnesium content. Analysis of data from the NHANES study found that US children ages 2 to 12 years who consumed three or more daily servings of whole grains had significantly increased magnesium intakes (84).

Sodium

The 2010 Dietary Guidelines for Americans recommend that children should limit their sodium intake to 1,500 mg/day to lower blood pressure and thus reduce their risk of cardiovascular and kidney diseases in adulthood (85). In 2004, the FNB set the AI for children by extrapolating from the adult AI using relative energy intakes. The AI for children 4 to 8 years is 1,000 mg/day, which translates to 2.5 grams of salt per day, and the AI for boys and girls 9 to 13 years is 1,200 mg/day, which translates to 3 grams of salt per day (86).

Zinc

The mineral zinc is essential for growth and development, immune function, neurological function, and reproduction. Zinc plays a number of catalytic, structural, and regulatory roles in cellular metabolism (see the article on Zinc). Zinc deficiency is a major public health concern and has been estimated to affect more than 2 billion people in less developed nations (87). Children are at increased risk for zinc deficiency, which can lead to delayed physical growth, impaired immunity, and possibly to delayed mental development. Mild forms of this mineral deficiency, which are common in both developing and developed nations, appear to have negative effects on growth and development (23, 88). However, the lack of a sensitive indicator of mild zinc deficiency hinders the scientific study of its health implications.

Mild zinc deficiency contributes to impaired physical growth in children (88, 89). Significant delays in linear growth and weight gain, known as growth retardation or failure to thrive, are common features of mild zinc deficiency in children. In the 1970s and 1980s, several randomized, placebo-controlled studies of zinc supplementation in young children with significant growth delays were conducted in Denver, Colorado. Modest zinc supplementation (5.7 mg/day) resulted in increased growth rates compared to placebo (89). More recently, a number of larger studies in developing countries observed similar results with modest zinc supplementation. A meta-analysis of growth data from zinc intervention trials recently confirmed the widespread occurrence of growth-limiting zinc deficiency in young children, especially in developing countries (90). Although the exact mechanism for the growth-limiting effects of zinc deficiency are not known, recent research indicates that zinc availability affects cell-signaling systems that coordinate the response to the growth-regulating hormone, insulin-like growth factor-1 (IGF-1) (91, 92).

Adequate zinc intake in children is essential in maintaining the integrity of the immune system (23, 93), and zinc deficiency is associated with increased susceptibility to a variety of infectious agents (94). The adverse effects of zinc deficiency on immune system function are likely to increase the susceptibility of children to infectious diarrhea, and persistent diarrhea contributes to zinc deficiency and malnutrition. It has been estimated that diarrheal diseases result in the deaths of about 3 million children each year (95). Zinc supplementation in combination with oral rehydration therapy has been shown to significantly reduce the duration and severity of acute and persistent childhood diarrhea and to increase survival in a number of randomized controlled trials (96, 97). Recently, a meta-analysis of randomized controlled trials concluded that zinc supplementation reduces the frequency, severity, and duration of diarrheal episodes in children under five years of age (98). The World Health Organization and the United Nations Children's Fund currently recommend zinc supplementation as part of the treatment for diarrheal diseases in young children (99). Zinc supplementation may also reduce the incidence of lower respiratory infections, such as pneumonia. A pooled analysis of a number of studies in developing countries demonstrated a substantial reduction in the prevalence of pneumonia in children supplemented with zinc (100). A recent meta-analysis found that zinc supplementation reduced the incidence but not duration of pneumonia or respiratory tract illnesses in children under five years of age (98). Due to conflicting reports (101-104), it is not yet clear whether zinc supplementation has utility in treating childhood malaria.

Because a sensitive indicator of zinc nutritional status is not readily available, the RDA for zinc was based on a number of different indicators of zinc nutritional status and represents the daily intake likely to prevent deficiency in nearly all individuals in a specific age and gender group. The RDA for children ages 4 to 8 years is 5 mg/day, and the RDA for boys and girls ages 9 to 13 years is 8 mg/day (105). Shellfish, beef, and other red meats are rich sources of zinc. Nuts and legumes are relatively good plant sources of zinc. Zinc bioavailability (the fraction of zinc retained and used by the body) is relatively high in meat, eggs, and seafood because of the relative absence of compounds that inhibit zinc absorption and the presence of certain amino acids (cysteine and methionine) that enhance zinc absorption. The zinc in whole-grain products and plant proteins is less bioavailable due to their relatively high content of phytic acid, a compound that inhibits zinc absorption (106). The enzymatic action of yeast reduces the level of phytic acid in foods. Therefore, leavened whole-grain breads have more bioavailable zinc than unleavened whole-grain breads (105).

Other Nutrients

Choline

Choline can be synthesized by the body in small amounts, but dietary intake is needed to maintain health (107). Choline and its metabolites have a number of essential biological functions. Choline is used in the synthesis of specific phospholipids (i.e., phosphatidylcholine and sphingomyelin) that are structural components of cell membranes and also precursors for certain cell-signaling molecules. Choline is needed for myelination of nerves and is a precursor for acetylcholine, a neurotransmitter involved in muscle action, memory, and other functions (108-110). For more information about the role of choline in the body, see the article on Choline.

Due to the lack of data in children, intake recommendations for choline in children were extrapolated from adult recommendations using metabolic body weight, accounting for growth. The AI for children aged 4 to 8 years is 250 mg/day, and the AI for boys and girls aged 9 to 13 years is 375 mg/day (108). A number of foods contain choline, but eggs, meats, and milk are the primary sources in the American diet (111).

Essential fatty acids

α-Linolenic acid (ALA), an omega-3 fatty acid, and linoleic acid (LA), an omega-6 fatty acid, are considered essential fatty acids because they cannot be synthesized by humans. The long-chain omega-6 fatty acid, arachidonic acid (AA), can be synthesized from LA, and two long-chain omega-3 fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), can be synthesized from ALA (112). These polyunsaturated fatty acids have a number of biological activities that are generally important for the structure and function of cell membranes, vision, eicosanoid synthesis, regulation of gene expression, and nervous system function (see the article on Essential Fatty Acids).

Dietary intake recommendations for ALA and LA in children were based on median intakes of American children, a population where omega-3 and omega-6 fatty acid deficiencies are not observed. The AI of ALA for children ages 4 to 8 years is 0.9 g/day, while the AI of ALA for children ages 9 to 13 years is 1.2 and 1.0 g/day for boys and girls, respectively. The long-chain omega-3 fatty acids, EPA and DHA, can contribute to these intake recommendations. Flaxseeds, walnuts, and their oils are among the richest dietary sources of ALA, but canola oil is also an excellent source of ALA. Oily fish, such as salmon, tuna, trout, and sardines, are the major dietary source of EPA and DHA (113). The AI of LA for children ages 4 to 8 years is 10 g/day, while the AI of LA for boys and girls ages 9 to 13 years is 12 and 10 g/day, respectively. Sources of LA include vegetable oils, such as soybean, safflower, and corn oil, nuts, seeds, and some vegetables (see the article on Essential Fatty Acids).

Safety

The FNB sets a tolerable upper intake level (UL) for most micronutrients. The UL is the highest level of daily nutrient intake likely to pose no risk of adverse health effects in almost all individuals of a specified age group. This level applies to total daily intake from food, water, and supplements. Due to the potential for adverse effects, it is recommended that individuals not exceed the UL. Thus, individuals should use the UL as a guide to limit daily micronutrient intake, not as a recommended level of intake (114). **Table 3** lists the UL for children ages 4 to 8 years, and **Table 4** lists the UL for children ages 9 to 13 years.

Table 3. Dietary Reference Intakes Set by the FNB:
UL for Micronutrients During Childhood, Ages 4 to 8 Years

Micronutrient	Males and Females
Biotin	ND^a
Folate	400 μg/day^b
Niacin	15 mg/day^b
Pantothenic Acid	ND
Riboflavin	ND
Thiamin	ND
Vitamin A	900 μg/day (3,000 IU/day)^c
Vitamin B$_6$	40 mg/day
Vitamin B$_{12}$	ND
Vitamin C	650 mg/day
Vitamin D	75 μg/day (3,000 IU/day)
Vitamin E	300 mg/day (450 IU/day)^d
Vitamin K	ND
Calcium	2,500 mg/day
Chromium	ND
Copper	3,000 μg/day
Fluoride	2.2 mg/day
Iodine	300 μg/day
Iron	40 mg/day
Magnesium	110 mg/day^e
Manganese	3 mg/day
Molybdenum	600 μg/day
Phosphorus	3,000 mg/day
Potassium	ND
Selenium	150 μg/day
Sodium	ND
Zinc	12 mg/day
Choline^f	1,000 mg/day
α-Linolenic Acid^f	Not established
Linoleic Acid^f	Not established

^{a}ND, not determinable
^{b}Applies to the synthetic form in fortified foods and supplements
^{c}Applies only to preformed retinol
^{d}Applies to any form of supplemental α-tocopherol
^{e}Applies only to the supplemental form
^{f}Considered an essential nutrient, although not strictly a micronutrient

Table 4. Dietary Reference Intakes Set by the FNB:
UL for Micronutrients During Childhood, Ages 9 to 13 Years

Micronutrient	Males and Females
Biotin	ND^a
Folate	600 μg/day^b
Niacin	20 mg/day^b

Pantothenic Acid	ND
Riboflavin	ND
Thiamin	ND
Vitamin A	1,700 μg/day (5,667 IU/day)[c]
Vitamin B_6	60 mg/day
Vitamin B_{12}	ND
Vitamin C	1,200 mg/day
Vitamin D	100 μg/day (4,000 IU/day)
Vitamin E	600 mg/day (900 IU/day)[d]
Vitamin K	ND
Calcium	3,000 mg/day
Chromium	ND
Copper	5,000 μg/day
Fluoride	10 mg/day
Iodine	600 μg/day
Iron	40 mg/day
Magnesium	350 mg/day[e]
Manganese	6 mg/day
Molybdenum	1,100 μg/day
Phosphorus	4,000 mg/day
Potassium	ND
Selenium	280 μg/day
Sodium	ND
Zinc	23 mg/day
Choline[f]	2,000 mg/day
α-Linolenic Acid[f]	Not established
Linoleic Acid[f]	Not established

[a] ND, not determinable
[b] Applies to the synthetic form in fortified foods and supplements
[c] Applies only to preformed retinol
[d] Applies to any form of supplemental α-tocopherol
[e] Applies only to the supplemental form
[f] Considered an essential nutrient, although not strictly a micronutrient

Note that many children's multivitamin/mineral supplements on the market contain more than the RDA for several micronutrients when taken at the suggested dosage by age. Some even contain micronutrients (e.g., vitamin A, folic acid, copper, and zinc) at levels equivalent to the UL; this concern is for children younger than 9 years old. The Food and Nutrition Board of the Institute of Medicine recommends that daily nutrient intake from food and supplements not exceed the UL for each micronutrient. There is no evidence that consumption of micronutrients at or above the UL results in any health benefits in children, and the UL should not be exceeded except under medical supervision. Children often consume vitamin and mineral-fortified foods like cereal, and their total intake of certain micronutrients like vitamin A, folic acid, copper, and zinc from fortified foods, other dietary intake, and from supplements should be determined to ensure that the UL is not exceeded. It is also important to note that the daily values (DVs) listed on supplement labels in the US do not reflect the current intake recommendations (RDA or AI). Another caution is that many children's supplements look like candy but should never be labeled as such and, because of safety concerns, should be kept out of reach of children.

Conclusion

A healthy diet in children is important to provide nutrients that support optimum physical growth and cognitive development and to also establish healthy eating behaviors that lower risk of chronic diseases in adulthood. Although it is generally advised that micronutrients should be obtained from food, many children do not reach daily intake recommendations for select micronutrients, including vitamins A, C, D, and E, and some minerals, such as calcium and magnesium (37, 115).

Therefore, the Linus Pauling Institute recommends that children ages 4 to 13 years take a daily multivitamin/mineral supplement with 100% of the daily value (DV) for most vitamins and essential minerals, keeping the following suggestions in mind:

- Since the DV for vitamin A for those ages 4 and older (5,000 IU) is considerably higher than the current RDA for children ages 4 to 8 years (1,333 IU/day) and 9 to 13 years (2,000 IU/day), LPI recommends looking for a children's multivitamin/mineral supplement containing no more than 2,500 IU (750 μg) of vitamin A, of which at least 50% comes from β-carotene.
- In general, multivitamin/mineral supplements contain only a small percentage of the RDA for calcium and magnesium; therefore, intake of calcium and magnesium from dietary sources, such as low-fat milk, is important. If the RDAs for these minerals (1,000 and 1,300 mg/day for calcium and 130 and 240 mg/day for magnesium for children 4 to 8 years and 9 to 13 years, respectively) are not met through diet plus the multivitamin/mineral supplement, LPI recommends an additional, combined calcium-magnesium supplement for children.
- Because there are limited dietary sources of vitamin D and many children use sunscreens, which block skin synthesis of vitamin D, LPI recommends that all children ages 4 to 13 years should have a daily intake of 600 to 1,000 IU (15 to 25 μg) of vitamin D, consistent with the recommendations of the Endocrine Society (39). Given the average vitamin D content in the diets of children, supplementation may be necessary to meet this recommendation.

Micronutrient Requirements of Adolescents Ages 14 to 18 Years

Introduction

Adolescence — the transitional stage of development between childhood and adulthood — is associated with marked physical growth, reproductive maturation, and cognitive transformations. Physical changes begin in early adolescence during puberty, when sexual maturity is reached and reproduction is possible (1). Girls generally begin their adolescent growth spurt at an earlier age (9 years of age) than boys (11 years of age); the pubertal growth spurt lasts between two to four years, with the average rate of linear growth being 5-6 cm/year (2-2.4 in/year). Boys experience greater gains in height compared to girls because of a higher rate of growth and a longer growth spurt (2). Gains in linear growth are accompanied by increases in body weight and changes in body composition. Weight gain in girls typically happens six months following the greatest gains in linear growth, whereas weight gain in boys is usually coincident with increases in height. Throughout adolescence, boys gain more lean (fat-free) mass than girls, and girls experience greater increases in adiposity, which is required for normal menstruation (3). Moreover, approximately half of adult bone mass is obtained during adolescence (4), with boys experiencing greater gains in bone size and bone mass compared to girls (5).

In addition to physical growth, reproductive maturation occurs during adolescence. Maturation of the reproductive organs and development of secondary sexual characteristics, including facial hair in males and breast development in females, take place during puberty. Girls also experience menarche — the first occurrence of menstruation — during this developmental stage, typically following the peak period of gains in height and weight (6). Adolescence is further characterized by cognitive, emotional, and psychosocial development (2).

Good nutrition is needed to support the growth and developmental changes of adolescence. Undernutrition, in general, has been shown to delay the adolescent growth spurt (7). Overnutrition, a form of malnutrition where macronutrients (carbohydrates, fats, proteins) are supplied in excess of the body's needs, can lead to obesity and is a concern in industrialized nations. In the developed world, adolescents are increasingly consuming energy-rich, nutrient poor diets comprised of fast food, processed foods, and sugar-sweetened beverages (8-10). Studies have also shown that many adolescents do not come close to meeting intake recommendations for nutrient-rich foods, such as fruit, vegetables, and milk (11, 12). Together, these dietary behaviors place adolescents at increased risk for micronutrient deficiencies. This article discusses micronutrient requirements of adolescents aged 14 to 18 years, an age range that is used by the Food and Nutrition Board (FNB) of the US Institute of Medicine to establish dietary reference intakes. Due to limited data, many of the micronutrient intake recommendations for adolescents are extrapolated from recommendations for adults using a formula that accounts for metabolic body weight and growth (13), not unique physiological changes during adolescence. Metabolic body weight is determined by calculating the 0.75 power of body mass (body mass^0.75) (14). To account for growth, the equation used to derive a Recommended Dietary Allowance (RDA) or Adequate Intake (AI) involves an age group-specific growth factor (13). The FNB set different micronutrient intake recommendations for children 9 to 13 years, an age range that encompasses puberty and early stages of adolescence (15); discussion of the micronutrient requirements of younger children is included in a separate article (see Micronutrient Needs of Children Ages 9 to 13 Years).

Micronutrient Needs of Adolescents Aged 14 to 18 Years

For each micronutrient, the FNB sets an RDA or AI for adolescents aged 14 to 18 years. These recommendations are gender specific to account for the unique nutritional needs of males and females as they undergo the physiological changes of adolescence. **Table 1** lists the RDA for each micronutrient by gender. The RDA should be used in the planning of diets for individuals. A more detailed discussion of the requirements of certain micronutrients for adolescents can be found below.

Table 1. Dietary Reference Intakes Set by the FNB:
RDA for Micronutrients During Adolescence, Ages 14 to 18 Years, Per Day

Micronutrient	Males	Females
Biotin	25 μg (AI)	25 μg (AI)
Folate	400 μg[a]	400 μg[a]
Niacin	**16 mg[b]**	**14 mg[b]**
Pantothenic Acid	5 mg (AI)	5 mg (AI)
Riboflavin	**1.3 mg**	**1.0 mg**
Thiamin	**1.2 mg**	**1.0 mg**
Vitamin A	**900 μg (3,000 IU)[c]**	**700 μg (2,333 IU)[c]**
Vitamin B_6	**1.3 mg**	**1.2 mg**
Vitamin B_{12}	2.4 μg	2.4 μg
Vitamin C	**75 mg**	**65 mg**
Vitamin D	15 μg (600 IU)	15 μg (600 IU)
Vitamin E	15 mg (22.5 IU)[d]	15 mg (22.5 IU)[d]
Vitamin K	75 μg (AI)	75 μg (AI)
Calcium	1,300 mg	1,300 mg
Chromium	**35 μg (AI)**	**24 μg (AI)**
Copper	890 μg	890 μg
Fluoride	3 mg (AI)	3 mg (AI)
Iodine	150 μg	150 μg
Iron	**11 mg**	**15 mg**
Magnesium	**410 mg**	**360 mg**
Manganese	**2.2 mg (AI)**	**1.6 mg (AI)**
Molybdenum	43 μg	43 μg
Phosphorus	1,250 mg	1,250 mg
Potassium	3,000 mg (AI)	2,300 mg (AI)
Selenium	55 μg	55 μg
Sodium	1,500 mg (AI)	1,500 mg (AI)
Zinc	**11 mg**	**9 mg**

RDA, recommended dietary allowance; AI, adequate intake
[a] Dietary Folate Equivalents
[b] NE, niacin equivalent: 1 mg NE = 60 mg tryptophan = 1 mg niacin
[c] Retinol Activity Equivalents
[d] α-Tocopherol

Vitamins

Vitamin A

Vitamin A is a fat-soluble vitamin that is essential for growth and development, normal vision, the expression of selected genes, immunity, and reproduction (16). Vitamin A deficiency in children and adolescents is a major public health problem worldwide, especially in less developed countries (17, 18). Even marginal or subclinical deficiencies in vitamin A may have adverse effects on bone growth and sexual maturation of adolescents (19). Because of its role in immunity, inadequate intake of this vitamin also increases risk for infectious diseases (20).

Studies in industrialized countries have reported inadequate intakes of vitamin A among adolescents (21-23). Serum retinol binding protein (RBP) concentrations have been shown to increase throughout the stages of puberty, indicating that vitamin A is needed for adolescent development (24). However, few vitamin A supplementation studies have been done in adolescents; most supplementation studies have included younger children who are more susceptible to vitamin A deficiency.

The RDA for vitamin A is based on the amount needed to ensure adequate stores (four months) of vitamin A in the body to support normal reproductive function, immune function, vitamin A-dependent gene expression, and vision (16). Vitamin A intake recommendations for adolescents were derived by extrapolating the recommendation for adults using metabolic body weight, accounting for growth. The RDA for adolescent boys aged 14 to 18 years is 900 μg per day of Retinol Activity Equivalents (RAE), which is 3,000 international units (IU); the RDA for adolescent girls aged 14 to 18 years is 700 μg of RAE, which is equivalent to 2,333 IU. For information on vitamin A content in foods, see the article on Vitamin A.

Vitamin B_6

Vitamin B_6 is required for heme synthesis and in the synthesis and metabolism of amino acids — the building blocks of proteins. Thus, the vitamin has obvious relevance to adolescent growth and health. Dietary intake recommendations of vitamin B_6 for adolescents were established by extrapolating data from adults, using metabolic body weight and accounting for growth. The RDA for boys aged 14 to 18 years is 1.3 mg/day, and the RDA for girls aged 14 to 18 years is 1.2 mg/day (25). Only a few studies have evaluated vitamin B_6 status specifically in adolescents. In an analysis of American adolescent girls (aged 12-16 years), mean dietary intake of vitamin B_6 was 1.2 mg/day; however, one-third of the girls not taking vitamin B_6-containing supplements had either marginal or deficient vitamin B_6 status (26). The same investigators found more than 40% vitamin B_6 inadequacy when a group of 112 adolescent girls (12- and 14-year-old) were followed for two years (27). Results of more recent studies have suggested that most American and European adolescents are meeting current intake recommendations for vitamin B_6 (28, 29), although a study in Canada found that more than half of adolescent males aged 14 to 18 years did not meet the Estimated Average Requirement (EAR) of 1.1 mg/day for vitamin B_6 (22). For information on dietary sources of the vitamin, see the article on Vitamin B_6.

Folate

The B vitamin, folate, is required as a coenzyme to mediate the transfer of one-carbon units. Folate coenzymes act as acceptors and donors of one-carbon units in a variety of reactions critical to the endogenous synthesis and metabolism of nucleic acids (DNA and RNA) and amino acids (30, 31). Thus, folate has obvious importance in growth and development. Moreover, higher intakes of folate in adolescents have been linked to better academic achievement (32). Like other B vitamins, adolescent intake recommendations for folate were extrapolated from adult recommendations, using metabolic body weight and accounting for growth. The RDA for adolescents aged 14 to 18 years is 400 μg/day of dietary folate equivalents (33).

When considering naturally occurring folate in foods, results of a national survey indicate that almost 80% of individuals aged 2-18 years in the US have intakes below the EAR, which is 330 μg/day of dietary folate equivalents for adolescents aged 14-18 years. However, when accounting for intake from fortified foods, less than 5% of individuals in that age group have intakes below the EAR (34). The US Food and Drug Administration implemented legislation in 1998 requiring the fortification of all enriched grain products with folic acid (35). Globally, more than 50 countries have mandatory programs of wheat-flour fortification with folic acid, but flour fortification is not common in Europe (36). Dietary folate inadequacy is common among adolescents in European nations, especially girls (29).

Vitamin B_{12}

Vitamin B_{12} is needed for two types of reactions in the human body. One is transmethylation (methyl transfer between two molecules) that leads to the synthesis of the amino acid methionine from homocysteine. Methionine, in turn, is required for the synthesis of S-adenosylmethionine, a methyl group donor used in many biological methylation reactions, such as the methylation of sites within DNA and RNA (37). The second sort of reaction is isomerization (rearrangement of a molecule). Vitamin B_{12} acts as a coenzyme for methylmalonyl-CoA mutase to convert methylmalonyl-CoA to succinyl-CoA, an important step for the metabolism of proteins and lipids. Both transmethylation and isomerization reactions are essential for the metabolism of components of the myelin sheath of nerve cells and for the metabolism of neurotransmitters. Accordingly, vitamin B_{12} deficiency damages the myelin sheath covering cranial, spinal, and peripheral nerves, resulting in neurological damage (38, 39). The myelin sheath is the insulating layer of tissue made up of lipids and proteins that surrounds nerve fibers. This sheath acts as a conduit in an electrical system, allowing rapid and efficient transmission of nerve impulses (40). In some cases, neurologic symptoms caused by vitamin B_{12} deficiency can be reversed by vitamin treatment (38), but reversibility seems to be dependent upon the duration of the associated neurologic complications (41).

Although myelination primarily occurs during fetal development and early infancy, it continues through childhood, adolescence, and stages of early adulthood (42, 43). Because of the role of vitamin B_{12} in myelination and other metabolic processes, it is important for adolescents to meet dietary intake recommendations. The RDA of vitamin B_{12} for adolescent boys and girls aged 14 to 18 years is 2.4 μg/day (41), extrapolated from the recommendation for adults.

Vitamin B_{12} is naturally present only in animal products, such as meat, poultry, fish (including shellfish), and to a lesser extent in milk, but it is not generally present in plant products or yeast (44). Vitamin B_{12} deficiency has been reported in adolescents on very restricted or strict vegetarian diets (45, 46). Because vitamin B_{12} is stored in the liver, it may take three to six years for clinical symptoms to manifest (45). Thus, adolescents who have vegan diets need adequate intake from fortified foods or supplemental vitamin B_{12}.

Vitamin C

Vitamin C has a number of important roles during growth and development, including being required for the synthesis of collagen, carnitine, and neurotransmitters (47). Vitamin C is also a highly effective antioxidant and is important for immunity (see the article on Immunity). Further, vitamin C strongly enhances the absorption of nonheme iron by reducing dietary ferric iron (Fe^{3+}) to ferrous iron (Fe^{2+}). Specifically, iron absorption is two- to three-fold higher with co-ingestion of 25 to 75 mg of vitamin C (48). This has special relevance to adolescent health, considering the fact that iron deficiency is prevalent among adolescents, especially girls (see the section on Iron). The RDA for adolescents aged 14 to 18 years, which was extrapolated from recommendations for adults based on relative body weight, is 75 mg/day and 65 mg/day of vitamin C for boys and girls, respectively (49).

Data on vitamin C intake among adolescents are limited, but a recent US national survey, the 2003-2004 National Health and Nutrition Examination Survey (NHANES), found that serum vitamin C concentrations of adolescents (aged 12-19 years) were lower in adolescents compared to younger children (6-11 years), and adolescent girls had higher levels than adolescent boys (50). In this analysis, 2.7% of adolescent boys and 3.9% of adolescent girls had overt vitamin C deficiency that could result in clinical symptoms of scurvy. A cross-sectional analysis of European adolescents (aged 12.5-17.5 years) also noted higher vitamin C status among adolescent girls compared to boys, and compared to the US survey, the prevalence of overt vitamin C deficiency was lower in European adolescents (51). For information on food sources, see the article on Vitamin C.

Vitamin D

Vitamin D is a fat-soluble vitamin that is essential for maintaining normal calcium metabolism and is therefore necessary for bone health. Severe vitamin D deficiency in infants and children results in the failure of bone to mineralize, leading to a condition known as rickets, but cases of rickets have also been reported during stages of puberty and adolescence (52-53). Rapidly growing bones are most severely affected by rickets. The growth plates of bones continue to enlarge, but in the absence of adequate mineralization, weight-bearing limbs (arms and legs) become bowed. Inadequate vitamin D during puberty and adolescence might prevent the attainment of peak bone mass and final height (54-56) and could possibly increase the risk of osteoporosis or other diseases in adulthood, but more studies on these associations are needed.

In 2010, the Food and Nutrition Board (FNB) of the Institute of Medicine set an RDA based on the amount of vitamin D needed for bone health and assuming minimal sun exposure; the RDA is 600 IU/day (15 μg/day) for adolescents aged 14 to 18 years. In the US, milk is voluntarily fortified with 400 IU (10 μg) of vitamin D per quart (946 mL); thus, adolescents would need to consume about 6 cups of milk daily to meet the RDA. Although fish is the best source of vitamin D in the diet, fortified foods and beverages are likely the major dietary source of vitamin D for US adolescents. In Canada, fortification of milk and margarine is mandatory, with milk containing 35-45 IU per 100 mL (331-426 IU per quart) and margarine containing 530 IU per 100 grams (57), but vitamin D fortification of foods is less common in European nations (58). In addition to diet, vitamin D can be endogenously synthesized in the skin upon exposure to ultraviolet-B radiation from sunlight; however, sunscreens effectively block skin synthesis of vitamin D and vitamin D synthesis is diminished in northern latitudes during winter (see the article on Vitamin D).

Analysis of data from NHANES 2005-2006 found that average total vitamin D intakes (from diet and supplements combined) in US adolescents (aged 14 to 18 years) were 6.9 μg/day (276 IU/day) for boys and 5.0 μg/day (200 IU/day) for girls — well below the current RDA. This analysis also found that 16% of adolescent boys and 27% of adolescent girls took vitamin D-containing supplements (59). Because sun exposure can substantially affect body vitamin D levels, measuring 25-hydroxyvitamin D — the major circulating form of vitamin D — is a more useful indicator of vitamin D status. However, studies assessing vitamin D status in adolescents have used various cutoffs to define vitamin D deficiency and insufficiency and there is no consensus of what level constitutes adequacy.

It is assumed that a dietary intake of 600 IU (15 μg)/day results in a serum 25-hydroxyvitamin D level of 20 ng/mL (50 nmol/L), which the FNB considers as the cut-off point for vitamin D adequacy (60). However, many researchers believe that higher levels may benefit health. NHANES found that more than 25% of US adolescents (12-19 years) had serum 25-hydroxyvitamin D concentrations lower than 20 ng/mL (50 nmol/L) and about 75% of adolescents had levels lower than 32 ng/mL (80 nmol/L) (61). Some studies have found a higher prevalence of vitamin D deficiency among European adolescents (19, 62). Ethnic and seasonal differences have also been reported, with higher levels in whites compared to blacks (61, 63) and in summertime compared to wintertime (62, 64, 65). Moreover, several studies have reported low vitamin D status among adolescents living in sunny climates (63, 66-68).

Oral vitamin D supplementation has been shown to improve vitamin D status among adolescents (69, 70), and one double-blind, placebo-controlled trial found that improvements in vitamin D status were accompanied by some musculoskeletal benefits in adolescent girls (70). Although more supplementation studies are needed, ensuring vitamin D adequacy throughout childhood and adolescence seems prudent. The Linus Pauling Institute recommends that adolescents aged 14 to 18 years should have a daily intake of 600 to 1,000 IU (15 to 25 μg) of vitamin D, consistent with the recommendations of the Endocrine Society (71). According to the Endocrine Society, at least 600 IU/day may be required to maximize bone health, and 1,000 IU/day may be needed to increase serum levels above 30 ng/mL (75 nmol/L) (71). Given the average vitamin D content of the diets of adolescents, supplementation may be necessary to meet this recommendation. The American Academy of Pediatrics currently suggests that all adolescents who do not get 400 IU/day of vitamin D through dietary sources should take 400 IU of supplemental vitamin D daily (72) — an amount that is typically found in multivitamin supplements.

Vitamin E

The RDA of vitamin E for adolescents, expressed as an amount of the α-tocopherol form of the vitamin, was based on extrapolations from intake recommendations for adults, accounting for differences in lean body mass and increased needs of growth during adolescence. The RDA is 15 mg/day (22.5 IU/day) for boys and girls ages 14 to 18 years (73). A US national survey, NHANES 1999-2000, found that adolescent boys and girls aged 14 to 18 years had average intakes of 7.5 mg/day and 5.7 mg/day of α-tocopherol, respectively. Moreover, 92% of adolescent boys and more than 99% of adolescent girls of this age group had daily intakes below the EAR of 12 mg/day (74). Vitamin E intake has been reported to be similarly low in adolescents in Spain (21), Switzerland (23), Brazil (75), France (76), and Germany (77). However, true vitamin E deficiency is rare and has been observed only in cases of severe malnutrition, genetic defects affecting the α-tocopherol protein, and fat malabsorption syndromes; see the article on Vitamin E.

Minerals

Calcium

About 99% of calcium in the body is found in bones and teeth (78). Adequate intake of calcium throughout childhood and adolescence is important for proper mineralization of growing bones, attainment of peak bone mass, and reduction of risk of bone fracture and osteoporosis in adulthood. Dietary intake recommendations for calcium in adolescents were established using a factorial method that summed average calcium accretion and calcium losses to urine, feces, and sweat and also adjusted for calcium absorption (60). Specifically, data used by the FNB to determine calcium accretion came from a recent longitudinal study in 642 Caucasian adolescents aged 14 to 18 years (79). The authors of this study estimated that the daily calcium requirement is higher in boys than girls; however, the FNB concluded that the differences were relatively small and it would be more practical to establish a single recommendation for all adolescents. Thus, the RDA was set at 1,300 mg/day; this level of calcium intake is expected to cover the needs of 97.5% of adolescents.

Many US adolescents have dietary calcium intakes below the RDA, with girls having lower intakes than boys. A recent analysis of data from NHANES 2003-2006, a US national survey, found that 42% of adolescent boys and only 10% of adolescent girls (14-18 years) had dietary calcium intakes above 1,300 mg/day. When accounting for use of calcium-containing supplements (19% and 24% of boys and girls, respectively; average supplemental intake of 142 and 182 mg/day of calcium in boys and girls, respectively), 42% of adolescent boys and only 13% of adolescent girls had total daily intakes above the current RDA (59). A recent publication that reviewed average calcium intake among adolescents in 23 nations found that boys generally have intakes of ~100-200 mg/day higher than girls and that many adolescents do not meet intake recommendations (80).

Dairy products, which provide about 72% of the calcium in the American diet (78), represent rich and absorbable sources of calcium. Milk contains 300 mg of calcium per cup; therefore, adolescents could meet the RDA for calcium by drinking 4.3 cups of low-fat milk daily. However, NHANES data show that US adolescents (12-19 years) on average consume only about 1 cup of milk daily (81). Lactose intolerance may prevent some adolescents from consuming milk, and consumption of soft drinks and other sweetened beverages might displace milk consumption in adolescents (82).

Certain vegetables and grains also provide calcium, but their bioavailability is lower compared with dairy. For more information on dietary sources of calcium and calcium bioavailability, see the article on Calcium. The Nutrition Facts label of packaged foods lists calcium content in one serving as a percent of the Daily Value (DV), with the DV being 1,000 mg. Since the RDA for adolescents is 1,300 mg/day, the percentage of the DV listed on the food label would be an overestimation of the percentage of the RDA. If adolescents do not meet the RDA through diet alone, LPI recommends supplemental calcium. Multivitamin/mineral supplements generally provide no more than 200 mg of calcium.

Iron

Iron is an essential component of hundreds of proteins and enzymes involved in various aspects of metabolism, including oxygen transport and storage, electron transport and energy metabolism, antioxidant and beneficial pro-oxidant functions, oxygen sensing, and DNA synthesis (44, 83-85); see the article on Iron. Iron deficiency, which is the most common nutritional deficiency in the world, is a major public health problem, especially in developing nations, but it is also prevalent in industrialized nations, notably in women of childbearing age. Severe iron deficiency leads to iron-deficiency anemia; anemia affects more than 30% of the global population (2 billion people) (81). Adolescents have increased requirements for iron due to rapid growth. In particular, adolescent girls are at a heightened risk of iron deficiency due to inadequate intake of dietary iron, especially heme iron; increased demands of growth; and iron loss that occurs with menstruation. Following puberty, adolescent girls have lower iron stores compared to adolescent boys (87).

In addition to the negative effects of iron deficiency on physical growth, iron deficiency during adolescence may impair immunity (see the article on Nutrition and Immunity) as well as cognition. Iron is needed for proper development of oligodendrocytes (the brain cells that produce myelin) (88), and the mineral is also a required cofactor for several enzymes that synthesize neurotransmitters (89). Iron deficiency — even levels not associated with anemia — during important stages of brain development, such as adolescence, may have detrimental consequences. A double-blind, placebo-controlled trial in 73 adolescent girls (aged 13-18 years) with non-anemic iron deficiency found that high-dose iron supplementation (260 mg/day of elemental iron) for eight weeks resulted in greater improvement in verbal learning but not in other cognitive domains (90). Another study reported that one-month iron supplementation beyond that included in a prenatal vitamin improved some measures of attention and short-term memory in young pregnant women (aged 14-24 years) without severe iron deficiency (91). Clinical trials of iron supplementation to date have been mostly done in other age groups; large, well-designed trials in adolescents are needed to determine the effects of iron supplementation on cognition.

Dietary intake recommendations for adolescents were based on a factorial modeling approach that accounts for the amount of iron needed to replace basal losses (losses in urine, feces, and sweat), iron requirements associated with growth (increases in hemoglobin and iron content of tissues), and iron losses associated with menstruation in girls. The intake recommendations also account for average bioavailability (the fraction of iron retained and used by the body) of dietary iron for this age group (92). The RDA of iron is 11 mg/day for adolescent boys and 15 mg/day for adolescent girls. A US national survey, NHANES 2001-2002, found that average dietary intake of iron was 19.1 mg/day in adolescent boys and 13.3 mg/day in adolescent girls; however, 16% of adolescent girls had intakes below the EAR of 7.9 mg/day. Because several different criteria have been used to identify iron deficiency, it is difficult to report the prevalence of iron deficiency among adolescents.

The amount of bioavailable iron in food (or supplements) is influenced by the iron nutritional status of the individual and also by the form of iron (heme or nonheme). Individuals who are anemic or iron deficient absorb a larger percentage of the iron they consume (especially nonheme iron) than individuals who are not anemic and have sufficient iron stores (94, 95). Heme iron, found in meat, poultry, and fish, is more readily absorbed, and its absorption is less affected by other dietary factors than nonheme iron — the form found in plants, dairy products, fortified foods, and supplements. Although heme iron generally accounts for only 10-15% of the iron found in the diet, it may provide up to one third of total absorbed dietary iron (83, 95). The absorption of nonheme iron is strongly influenced by enhancers and inhibitors present in the same meal. For instance, vitamin C strongly enhances the absorption of nonheme iron by reducing dietary ferric iron (Fe3+) to ferrous iron (Fe2+) and forming an absorbable, iron-ascorbic acid complex. Organic acids, such as citric, malic, tartaric, and lactic acids, also enhance nonheme iron absorption. Further, consumption of meat, poultry, and fish enhance nonheme iron absorption, but the mechanism for this increase in absorption is not clear (92, 94). Inhibitors of nonheme iron absorption include phytic acid, which is present in legumes, grains, and rice. Polyphenols found in some fruit, vegetables, coffee, tea, wines, and spices can also markedly inhibit the absorption of nonheme iron, but this effect is reduced by the presence of vitamin C (92, 96). Soy protein, such as that found in tofu, has an inhibitory effect on iron absorption that is independent of its phytic acid content (92).

Magnesium

The mineral magnesium is involved in more than 300 essential metabolic reactions that are generally involved in energy production and the synthesis of nucleic acids (DNA and RNA), proteins, carbohydrates, and lipids (97). Magnesium also plays structural roles in bone, cell membranes, and chromosomes and is also required for various cellular processes, including ion transport across cell membranes, cell signaling, and cell migration (98).

The RDA of magnesium for those aged 14 to 18 years, 410 mg/day for boys and 360 mg/day for girls, was derived from results of balance studies in adolescents. Good dietary sources of magnesium include nuts, and green leafy vegetables because magnesium is part of chlorophyll — the green pigment in plants. Meats and milk have an intermediate magnesium content, with milk providing 24-39 mg per cup (97). Refined foods generally have the lowest magnesium content. Although data are limited, some studies have found that a large percentage of adolescents have magnesium intakes below recommended levels (100-102). Data on magnesium intake among adolescents are lacking. In an analysis of NHANES data, US adolescents who consumed milk (plain or flavored) had higher daily magnesium intakes than adolescents who did not drink milk (103). However, NHANES data show that US adolescents (12-19 years) on average only consume about 1 cup of milk daily (81). Low-fat milk, nuts, whole grains, and green leafy vegetables are important sources of magnesium for adolescents. If adolescents do not meet the RDA through dietary sources, LPI recommends a combined magnesium-calcium supplement.

Potassium

Potassium is required for maintenance of cellular membrane potential and thus for nerve impulse transmission, muscle contraction, and heart function. In general, adolescents have low intakes of fruit, vegetables, and dairy products (104-106) — foods that are rich in potassium. Low intakes of potassium, coupled with high intakes of sodium (see section on Sodium), have been linked to elevations in blood pressure and a heightened risk of hypertension and stroke later in life (see the article on Potassium). In a study that followed 2,368 adolescent girls for nine years, lower intakes of potassium were associated with a higher incidence of hypertension (107). Fruit, vegetables, low-fat milk, and nuts are all good sources of potassium, and increasing intake of these foods during adolescence should help regulate blood pressure and may decrease risk of chronic disease during adulthood.

Sodium

In 2019, the FNB set the AI for adolescents by extrapolating from the adult AI using relative energy intakes; however, since energy intakes of adolescents are similar to that of adults, the recommendations are identical: 1,500 mg/day of sodium (108). The 2010 Dietary Guidelines for Americans recommend limiting sodium intake to 1,500 mg/day to lower blood pressure and thus reduce risk of cardiovascular disease and kidney diseases in adulthood. However, daily sodium intake in US adolescents (aged 12-19 years) is 3,000 mg in girls and 4,000 mg/day in boys (109). Low-sodium interventions in adolescents have shown some improvement in blood pressure, but compliance to such a diet is problematic (110, 111).

Zinc

The mineral zinc is essential for growth and development, immune function, neurological function, and reproduction. Zinc plays a number of catalytic, structural, and regulatory roles in cellular metabolism (see the article on Zinc). Zinc deficiency, which is estimated to affect more than 2 billion people in less developed nations (112), can retard normal growth, impair cognitive development, and delay sexual maturation (113, 114). Adolescents are at increased risk of zinc deficiency due to the demands of growth (115). Mild zinc deficiency, which is common in both the developing and developed world, may also have negative effects on growth and development (47, 116); however, the lack of a sensitive indicator of mild zinc deficiency hinders the scientific study of its health implications.

Because a sensitive indicator of zinc nutritional status is not readily available, the RDA for zinc was based on a number of different indicators of zinc nutritional status and represents the daily intake likely to prevent deficiency in nearly all individuals in a specific age and gender group. The RDA for adolescent boys and girls, aged 14 to 18 years, is 11 mg/day and 9 mg/day, respectively (113). A US national survey, NHANES 2001-2002, found that average dietary intake of zinc was 15.1 mg/day in adolescent boys and 9.5 mg/day in adolescent girls; only 4% of adolescent boys had intakes less than the EAR (8.5 mg/day), but 26% of adolescent girls had intakes less than the EAR (7.3 mg/day).

Shellfish, beef, and other red meats are rich sources of zinc; nuts and legumes are relatively good plant sources of zinc. Zinc bioavailability (the fraction of zinc retained and used by the body) is relatively high in meat, eggs, and seafood because of the relative absence of compounds that inhibit zinc absorption and the presence of certain amino acids (cysteine and methionine) that enhance zinc absorption. However, the zinc in whole-grain products and plant proteins is less bioavailable due to their relatively high content of phytic acid, a compound that inhibits zinc absorption (117). The enzymatic action of yeast reduces the level of phytic acid in foods. Therefore, leavened whole-grain breads have more bioavailable zinc than unleavened whole-grain breads (113).

Adolescent Pregnancy

Pregnancy during adolescence — a time when the girl is still growing herself — has been associated with increased risk of miscarriage, prematurity, low birth weight infants (<2,500 grams), and increased maternal and neonatal mortality (2, 118-119). Pregnant adolescents are also at a heightened risk for pregnancy-related complications, including pregnancy-induced hypertension and anemia (119). Because they are growing themselves, it is extremely important for pregnant adolescents to meet dietary intake recommendations. Recommendations for some key micronutrients needed for adolescent growth, including calcium, magnesium, phosphorus, and zinc, are higher than those for older pregnant women; see the discussion of Micronutrient Requirements During Pregnancy in a separate article. Pregnant adolescents are at increased risk for select micronutrient inadequacies, especially iron, zinc, calcium, magnesium, folate, vitamin B_6, vitamin D, and vitamin E (2, 120-121). Adequate nutrition is important not only for a healthy pregnancy outcome but also for the overall and skeletal health of the adolescent. A recent cross-sectional study of 719 postmenopausal women associated their pregnancy during adolescence with lower bone mineral density at several sites and a two-fold higher risk of osteoporosis compared to women without a history of adolescent pregnancy (122). However, it is not known whether adequate calcium intake during adolescent pregnancy might prevent age-related declines in bone mineral density or osteoporosis.

Safety

The FNB establishes a tolerable upper intake level (UL) for most micronutrients. The UL is the highest level of daily nutrient intake likely to pose no risk of adverse health effects in almost all individuals of a specified age group. This level applies to total daily intake from food, water, and supplements. Due to the potential for adverse effects, it is recommended that individuals not exceed the UL. Thus, individuals should use the UL as a guide to limit daily micronutrient intake, not as a recommended level of intake (123). There is no evidence that consumption of micronutrients at or above the UL results in any health benefits for adolescents, and the UL should not be exceeded except under medical supervision. **Table 2** lists the UL for adolescents.

Table 2. Dietary Reference Intakes Set by the FNB: UL for Micronutrients During Adolescence, Ages 14 to 18 Years, Per Day

Micronutrient	Males and Females
Biotin	ND[a]
Folate	800 μg[b]
Niacin	30 mg[b]
Pantothenic Acid	ND
Riboflavin	ND
Thiamin	ND
Vitamin A	2,800 μg (9,333 IU)[c]
Vitamin B_6	80 mg
Vitamin B_{12}	ND
Vitamin C	1,800 mg
Vitamin D	100 μg (4,000 IU)
Vitamin E	800 mg (1,200 IU)[d]
Vitamin K	ND
Calcium	3,000 mg
Chromium	ND
Copper	8,000 μg
Fluoride	10 mg
Iodine	900 μg
Iron	45 mg
Magnesium	350 mg[e]
Manganese	9 mg
Molybdenum	1.7 mg
Phosphorus	4,000 mg
Potassium	ND
Selenium	400 μg
Sodium	2,300 mg
Zinc	34 mg

[a] ND, not determinable
[b] Applies to the synthetic form in fortified foods and supplements
[c] Applies only to preformed retinol
[d] Applies to any form of supplemental α-tocopherol

[e]Applies only to the supplemental form

Conclusion

A healthy diet throughout puberty and adolescence is important to provide nutrients that support optimal physical growth and cognitive development. Although it is generally advised that micronutrients should be obtained from food, many adolescents do not reach daily intake recommendations for select micronutrients from diet alone. Therefore, the Linus Pauling Institute recommends that adolescents aged 14 to 18 years take a daily multivitamin/mineral supplement with 100% of the daily value (DV) for most vitamins and essential minerals, keeping the following suggestions in mind:

- Since the DV for vitamin A for those ages 4 and older (5,000 IU) is considerably higher than the current RDA for adolescents aged 14 to 18 years (3,000 IU/day for boys and 2,333 IU/day for girls), LPI recommends looking for a multivitamin/mineral supplement that provides no more than 2,500 IU (750 µg) of preformed vitamin A (usually labeled as vitamin A acetate or vitamin A palmitate) and no more than 2,500 IU of additional vitamin A as β-carotene.
- In general, multivitamin/mineral supplements contain only a small percentage of the RDA for calcium and magnesium; therefore, intake of calcium and magnesium from dietary sources, such as low-fat milk, is important. If the RDAs for these minerals (1,300 mg/day for calcium; 410 and 360 mg/day for magnesium for adolescent boys and girls, respectively) are not met through diet plus the multivitamin/mineral supplement, LPI recommends an additional, combined calcium-magnesium supplement for adolescents.
- Because there are limited dietary sources of vitamin D and many adolescents use sunscreens, which block skin synthesis of vitamin D, LPI recommends that all adolescents aged 14 to 18 years should have a daily intake of 600 to 1,000 IU (15 to 25 µg) of vitamin D, consistent with the recommendations of the Endocrine Society (71). Given the average vitamin D content in the diets of adolescents, supplementation may be necessary to meet this recommendation.

Micronutrient Needs During Pregnancy and Lactation

Introduction

Nutrient needs during the life stages of pregnancy and lactation are increased relative to women who are not pregnant or lactating. Mathematical models predict that energy requirements increase by an estimated 300 kcal/day during the second and third trimesters of pregnancy and by 500 kcal/day during lactation (1). In practice, most women will require only approximately 200 additional kcal/day due to reduced levels of physical activity during pregnancy and to increased lipolysis of fat stores during breast-feeding [personal communication with Dr. Berthold Koletzko]. Relative to the increased energy requirement, the requirements for many micronutrients (vitamins and nutritionally essential minerals) are even higher during pregnancy and lactation; this article discusses micronutrient needs during these life stages.

Micronutrient Requirements During Pregnancy

Pregnancy is associated with increased nutritional needs due to physiologic changes of the woman and the metabolic demands of the embryo/fetus. Proper maternal nutrition during pregnancy is thus imperative for the health of both the woman and the offspring. Maternal malnutrition during pregnancy has been associated with adverse outcomes, including increased risk of maternal and infant mortality, as well as low-birth-weight newborns (<2,500 grams) — a measure that accounts for preterm birth and intrauterine growth restriction of the fetus (2, 3). Select nutrient deficiencies have also been linked to congenital anomalies and birth defects. In addition, gestational undernutrition has been implicated in increasing the offspring's susceptibility to chronic disease (i.e., type 2 diabetes, hypertension, coronary heart disease, and stroke) in adulthood, a phenomenon sometimes called Barker's hypothesis, the thrifty phenotype hypothesis, or the fetal origin of adult disease hypothesis (4, 5). Maternal undernutrition often refers to malnutrition caused by insufficient caloric (energy) intake from macronutrients (carbohydrates, proteins, and lipids) during pregnancy, but micronutrient deficiencies are also a form of undernutrition. Multiple micronutrient deficiencies commonly co-exist in pregnant women (6).

Daily requirements for many micronutrients during pregnancy are higher to meet the physiologic changes and increased nutritional needs of pregnancy. Good nutritional status prior to conception is also important for a healthy pregnancy. For instance, folic acid supplementation during the periconceptional period (about one month before conception until the end of the first trimester) dramatically reduces the incidence of devastating birth defects called neural tube defects (see Folate below). Thus, folic acid supplementation (at least 400 µg/day) is recommended for all women capable of becoming pregnant (7-9). A well-balanced diet throughout pregnancy is necessary to supply the developing embryo/fetus with micronutrients. In addition to folic acid supplementation, iron supplementation is generally needed to meet the increased demands for this mineral during pregnancy (see the section on Iron below).

The Food and Nutrition Board (FNB) of the Institute of Medicine establishes life-stage specific dietary reference intakes (DRIs) for each micronutrient; these reference values should be used to plan and assess dietary intakes in healthy people (10, 11). The DRIs include the estimated average requirement (EAR), the recommended dietary allowance (RDA), the adequate intake (AI), and the tolerable upper intake level (UL). The RDA, which is the average daily dietary intake level of a nutrient sufficient to meet the requirements of almost all (97.5%) healthy individuals in a specific life stage and gender group, should be used in the planning of diets for individuals (12). The FNB establishes an AI when an RDA cannot be determined. The below recommendations are specific to the life stages of pregnancy and lactation. For most micronutrients, the RDA or AI for pregnant women is increased compared to nonpregnant women of the same age (**Table 1**). The discussion below largely focuses on these recommendations for select micronutrients during pregnancy but also notes major concerns for micronutrient toxicity or teratogenicity. The UL is the highest level of daily intake that is likely to pose no risk of adverse health effects in almost all individuals of a specified life stage. For the UL for each micronutrient during pregnancy, see **Table 2**.

Table 1. RDA for Micronutrients During Pregnancy

Micronutrient	Age	RDA
Biotin	14-50 years	30 µg/day (AI)
Folate	14-50 years	600 µg/day[a]
Niacin	14-50 years	18 mg/day[b]
Pantothenic Acid	14-50 years	6 mg/day (AI)
Riboflavin	14-50 years	1.4 mg/day
Thiamin	14-50 years	1.4 mg/day
Vitamin A	14-18 years	750 µg (2,500 IU)/day[c]
	19-50 years	770 µg (2,567 IU)/day[c]
Vitamin B_6	14-50 years	1.9 mg/day
Vitamin B_{12}	14-50 years	2.6 µg/day
Vitamin C	14-18 years	80 mg/day
	19-50 years	85 mg/day
Vitamin D	14-50 years	15 µg (600 IU)/day
Vitamin E	14-50 years	15 mg (22.5 IU)/day[d]
Vitamin K	14-18 years	75 µg/day (AI)
	19-50 years	90 µg/day (AI)
Calcium	14-18 years	1,300 mg/day
	19-50 years	1,000 mg/day
Chromium	14-18 years	29 µg/day (AI)
	19-50 years	30 µg/day (AI)
Copper	14-50 years	1 mg/day
Fluoride	14-50 years	3 mg/day (AI)
Iodine	14-50 years	220 µg/day
Iron	14-50 years	27 mg/day
Magnesium	14-18 years	400 mg/day
	19-30 years	350 mg/day
	31-50 years	360 mg/day
Manganese	14-50 years	2 mg/day (AI)
Molybdenum	14-50 years	50 µg/day
Phosphorus	14-18 years	1,250 mg/day
	19-50 years	700 mg/day
Potassium	14-18 years	2,600 mg/day (AI)
	19-50 years	2,900 mg/day (AI)
Selenium	14-50 years	60 µg/day
Sodium	14-50 years	1,500 mg/day (AI)
Zinc	14-18 years	12 mg/day
	19-50 years	11 mg/day
Choline[e]	14-50 years	450 mg/day (AI)

AI, adequate intake
[a]Dietary Folate Equivalents
[b]NE, niacin equivalent: 1 mg NE = 60 mg tryptophan = 1 mg niacin
[c]Retinol Activity Equivalents
[d]α-Tocopherol
[e]Considered an essential nutrient, although not strictly a micronutrient

Vitamins

Biotin

Biotin is needed as a cofactor for carboxylase enzymes and for the attachment of biotin to molecules, such as proteins, in a process known as "biotinylation" (13). Rapidly dividing cells of the developing fetus require the vitamin for synthesis of essential carboxylase enzymes and for histone biotinylation. Although maternal biotin deficiency in certain strains of mice causes malformations in the offspring, namely cleft palate and limb shortening (14, 15), a link between biotin deficiency and birth defects in humans has not been observed.

Experimentally induced, marginal biotin deficiency results in the increased urinary excretion of 3-hydroxyisovaleric acid (3-HIA) and decreased urinary excretion of biotin and the biotin catabolites, bisnorbiotin (BNB) and biotin disulfoxide (BSO) (16, 17). Abnormally elevated urinary excretion of 3-HIA and abnormally decreased urinary excretion of biotin are the most extensively validated biomarkers of low biotin status (18).

Two observational studies have reported that there is an increased urinary excretion of 3-HIA during pregnancy, though other indices of biotin status were not consistently altered (19, 20). Similarly, a 2014 feeding study in which all subjects consumed a mixed diet with a known amount of biotin (average daily intake, 57 µg biotin/day), urinary 3-HIA excretion was higher in pregnant compared to nonpregnant women, while urinary biotin and BNB excretion did not differ between the groups (21). Supplementation with biotin (300 µg/day for 14 days) reduced urinary 3-HIA and increased urinary biotin excretion in pregnant women with elevated 3-HIA; however, this intervention did the same for nonpregnant controls considered to have normal biotin status (22).

Elevated urinary excretion of 3-HIA during pregnancy could be due to several possibilities. Some suggest that it reflects marginal biotin deficiency and the need for more biotin during pregnancy (23, 24). Alternatively, increased 3-HIA in isolation could reflect altered leucine metabolism or renal handling of organic acids during pregnancy (18).

At this time, the AI for biotin (30 µg/day) is the same for pregnant and nonpregnant women. Biotin is widespread in food, though its concentration varies substantially (see the article on Biotin). Based on dietary intake data from the National Health and Nutrition Examination Survey (NHANES) II (18, 25) and the above-mentioned feeding study (21), a typical mixed diet provides approximately 40 to 60 µg of biotin/day.

Folate

The terms folate and folic acid are often used interchangeably, but folic acid is the synthetic form of the vitamin that is only found in fortified food and supplements. Folic acid is more bioavailable than folate from food (see the article on Folate); folic acid is converted to biologically active forms of folate in the body. Folate is needed for amino acid and nucleic acid (DNA and RNA) metabolism. Adequate folate status is critical to embryonic and fetal growth — developmental stages characterized by accelerated cell division. In particular, folate is needed for closure of the neural tube early in pregnancy, and periconceptional supplementation with folic acid has been shown to dramatically reduce the incidence of neural tube defects (NTDs) (reviewed in 26 and 27). NTDs are devastating congenital malformations that can occur as either anencephaly or spina bifida. Because these birth defects occur between 21 to 27 days after conception (28), often before many women recognize their pregnancy, it is recommended in the US that all women capable of becoming pregnant take supplemental folic acid (7).

A recent systematic review of five trials, including 7,391 women, found that periconceptional folic acid supplementation, alone or with other micronutrients, was associated with a 69% lower risk of NTDs (risk ratio (RR), 0.31; 95% confidence interval (CI), 0.17 to 0.58) (29). The RDA for pregnant women is 600 µg/day of dietary folate equivalents (DFE), which is equivalent to 300 µg/day of synthetic folic acid on an empty stomach or 353 µg/day of synthetic folic acid with a meal (see the article on Folate). The US Preventive Services Task Force recommends a daily supplement of 400-800 µg of folic acid, in addition to consuming food folate from a varied diet, for all women planning or capable of pregnancy (9). Supplemental folic acid use at the higher end of this suggested range has been recommended by some (27, 30), and 800 µg/day from supplements plus dietary intake is safe for women of childbearing age.

Multivitamin/mineral supplements marketed in the US commonly contain 400 µg of folic acid, and many prenatal supplements marketed in the US contain 800 µg of folic acid. Folic acid may also be present in the food supply: several countries have programs of mandatory folic acid fortification to help reduce the incidence of NTDs; for example, the US FDA implemented legislation in 1998 requiring the fortification of all enriched grain products with folic acid at a level of 140 µg folic acid/100 g of product (31). Mandatory fortification in the US has resulted in a 28 percent reduction (an estimated 1,326 births/year) in the prevalence of NTDs (32).

Doses greater than 1 mg/day of folic acid are used pharmacologically to treat hyperhomocysteinemia and to prevent reoccurrence of NTDs (33). Women who have had a previous NTD-affected pregnancy may be advised to consume up to 4 to 5 mg/day (4,000 to 5,000 µg/day) of folic acid if they are planning a pregnancy, but this level of supplementation should be prescribed by their medical provider (see the CDC recommendations and the World Health Organization [WHO] guidelines).

A new form of folate, 5-methyltetrahydrofolate (5-MTHF), has been proposed as an alternative to folic acid. 5-MTHF is less likely to mask a severe vitamin B_{12} deficiency, exhibits lower interaction potential with antimalarial drugs, and may be preferable for women with an MTHFR polymorphism (26, 34). While the effect of 5-MTHF supplementation on NTDs has not yet been evaluated, it is at least as effective as folic acid at raising red blood cell folate status and reducing homocysteine concentrations in nonpregnant healthy young women (35-38) and lactating women (39).

Inadequate folate status may also be linked to other birth defects, such as cleft lip, cleft palate, and limb malformations, but there are insufficient data to evaluate the effect of folic acid supplementation on these outcomes (26). However, results of some case-control studies (40-44) and controlled trials (45, 46) have suggested that periconceptional supplementation with a multivitamin containing folic acid may protect against congenital cardiovascular malformations, especially conotruncal (outflow tract) and ventricular septal defects. A 2006 systematic review and meta-analysis concluded that such supplementation was associated with a 22% lower risk of cardiovascular defects in case-control studies and a 39% lower risk in cohort studies and randomized controlled trials (47).

Impaired folate status during pregnancy may also be associated with other adverse pregnancy outcomes. Elevated blood homocysteine concentrations, considered an indicator of functional folate deficiency, have been associated with increased risk of preeclampsia, premature delivery, low placental weight, low birth weight, very low birth weight (<1,500 grams), small for gestational age, neural tube defects (NTDs), and stillbirth (48-50). Thus, it is reasonable to maintain folic acid supplementation throughout pregnancy, even after closure of the neural tube, in order to decrease the risk of other potential problems during pregnancy.

Riboflavin

Riboflavin is a component of flavocoenzymes involved in energy metabolism, as well as antioxidant functions. The Food and Nutrition Board of the Institute of Medicine recommends that all pregnant women consume 1.4 mg of riboflavin daily. Riboflavin deficiency has been implicated in preeclampsia — a pregnancy-associated complication characterized by elevated blood pressure, protein in the urine, and edema (significant swelling). Preeclampsia is estimated to affect 2%-8% of all pregnancies (51), and about 5% of women with preeclampsia progress to eclampsia, a significant cause of maternal death (52). Eclampsia is characterized by seizures, in addition to high blood pressure and increased risk of hemorrhage (severe bleeding) (52). Although the specific causes of preeclampsia are not known, decreased intracellular concentrations of flavocoenzymes could cause mitochondrial dysfunction, increase oxidative stress, and interfere with nitric oxide release and thus blood vessel dilation. All of these changes have been associated with preeclampsia, but there have been few studies on the association of riboflavin nutritional status and the condition. A study in 154 pregnant women at high risk for preeclampsia found that those who were riboflavin deficient were 4.7 times more likely to develop preeclampsia than those who had adequate riboflavin nutritional status (53). However, a small randomized, double-blind, placebo-controlled trial in 450 pregnant women at high risk for preeclampsia found that supplementation with 15 mg of riboflavin daily did not prevent the condition (54).

Vitamin A

Adequate maternal status of vitamin A is critical for a healthy pregnancy. Forms of the vitamin, known as retinoids, are involved in the regulation of gene expression, cellular proliferation and differentiation, growth and development, vision, and immunity (see the article on Vitamin A). The retinoids, retinol and retinoic acid, are essential for embryonic and fetal development (55); for example, retinoic acid functions in forming the heart, eyes, ears, and limbs (56). Animal studies demonstrate that severe vitamin A deficiency or excess during critical periods of development results in a spectrum of malformations, especially affecting craniofacial structures, limbs, and visceral organs (57).

Forms of vitamin A are also necessary for maternal health. Vitamin A deficiency during pregnancy has been linked to impaired immunity, increased susceptibility to infection, increased risk of maternal morbidity and mortality (58-61), and night blindness (62). Vitamin A deficiency may exacerbate iron-deficiency anemia (see section on Iron below); co-supplementation with vitamin A and iron seems to ameliorate anemia more effectively than either micronutrient supplement alone (63). Vitamin A deficiency is a major public health problem in developing nations, where availability of foods containing preformed vitamin A (retinol) and provitamin A carotenoids is limited (for information on food sources of vitamin A, see the article on Vitamin A). The RDA during pregnancy is 750 to 770 µg/day (2,500 to 2,567 IU/day) of preformed vitamin A (see **Table 1** above).

Although normal embryonic and fetal development require sufficient maternal vitamin A intake, consumption of excess preformed vitamin A during pregnancy causes birth defects. An increased risk of vitamin A-associated birth defects has not been observed at supplemental doses below 3,000 µg (10,000 IU)/day of preformed vitamin (64). However, because a number of foods in the US are fortified with preformed vitamin A, the Linus Pauling Institute recommends that pregnant women avoid multivitamin or prenatal supplements that contain more than 750 µg (2,500 IU) of preformed vitamin A. Vitamin A from β-carotene is not known to increase the risk of birth defects (58), although the safety of high-dose β-carotene supplements in pregnancy has not been well studied. Moreover, pharmacological use of retinoids by pregnant women causes serious birth defects; thus, tretinate, isotretinoin (Accutane), and other retinoids should not be used during pregnancy or if there is a possibility of becoming pregnant (65). Use of tretinoin (Retin-A), a topically applied retinoid, exhibits very low systemic absorption, but is not recommended during pregnancy due to possible risks (66). It is important to note that retinoids tend to be very long acting; birth defects have been reported to occur months after discontinuing retinoid therapy (57). Retinoids are used therapeutically to treat retinitis pigmentosa, acute promyelocytic leukemia, various skin diseases, and other conditions.

Vitamin B_6

Vitamin B_6 has diverse roles in the body, including nervous system function, red blood cell formation and function, steroid hormone function, nucleic acid synthesis, and niacin formation. Pyridoxal, pyridoxine, and pyridoxamine are three forms of the vitamin. The RDA for vitamin B_6 during pregnancy is 1.9 mg/day. Vitamin B_6 has been used since the 1940s to treat nausea during pregnancy. The results of two double-blind, placebo-controlled trials that used 25 mg of pyridoxine every eight hours for three days (67) or 10 mg of pyridoxine every eight hours for five days (68) suggest that vitamin B_6 may be beneficial in alleviating morning sickness. Each study found a slight but significant reduction in nausea or vomiting in pregnant women. A third randomized trial compared high-dose (10 mg/day) and low-dose (1.28 mg/day) vitamin B_6 in 60 pregnant women experiencing nausea and/or vomiting prior to the twelfth week of gestation (69). After two weeks, nausea and vomiting scores decreased to an equal extent in both supplementation groups. A 2014 pooled analysis indicates that supplemental vitamin B_6 alone may be effective in alleviating nausea, but not vomiting, during pregnancy (70). Vitamin B_6 at the above-mentioned dosages is considered safe during pregnancy, and the vitamin has been used in pregnant women without any evidence of fetal harm (68, 71).

Vitamin B_6 was included in the medication Bendectin (a delayed-release formulation of 10 mg doxylamine succinate [an antihistamine] and 10 mg pyridoxine hydrochloride [vitamin B_6]), which was prescribed for the treatment of morning sickness and later withdrawn from the market in 1983 due to unproven concerns that it increased the risk of birth defects (72). Since that time, several investigations have shown the combination of doxylamine/pyridoxine to be both effective and safe, and in 2013, the US Food and Drug Administration approved this same formulation for the treatment of nausea and vomiting in pregnancy (reviewed in 73 and 74). The American and Canadian Colleges of Obstetrics and Gynecology and the Association of Professors of Gynecology and Obstetrics recommend the combination of doxylamine/pyridoxine as first-line therapy for nausea and vomiting during pregnancy (reviewed in 75).

The tolerable upper intake level (UL) for vitamin B_6 during pregnancy is 80 to 100 mg/day; see **Table 2**.

Vitamin B_{12}

In humans, vitamin B_{12} is needed as a cofactor for two enzymes. One converts homocysteine to the amino acid, methionine. Methionine is required for the synthesis of S-adenosylmethionine, a methyl group donor used in many biological methylation reactions (76). DNA methylation that occurs during embryonic and fetal development modulates gene expression, cell differentiation, and the formation of organs (77). Thus, adequate vitamin B_{12} status during pregnancy is critical.

Inadequate dietary intake of vitamin B_{12} causes elevated homocysteine concentrations, which have been associated with adverse pregnancy outcomes, including preeclampsia, premature delivery, low placental weight, low birth weight, very low birth weight (<1,500 grams), small for gestational age, neural tube defects (NTDs), and stillbirth (48-50). Moreover, low serum concentrations of vitamin B_{12} during pregnancy have been linked to an increased risk for NTDs (78), and there is concern that folic acid supplementation during pregnancy may mask the clinical diagnosis of vitamin B_{12} deficiency. For these reasons, adequate vitamin B_{12} intake during pregnancy (RDA=2.6 µg/day) is important.

To ensure a daily intake of 6 to 30 µg of vitamin B_{12} in a form that is easily absorbed, the Linus Pauling Institute recommends that women who are planning a pregnancy take a daily multivitamin supplement or eat a breakfast cereal fortified with vitamin B_{12} (for more information, see the article on Vitamin B_{12}).

Vitamin C and Vitamin E

Because oxidative stress has been implicated in the pathogenesis of preeclampsia (79), nutritional status of the two antioxidant vitamins, vitamin C and vitamin E, may be important in preventing the condition. These vitamins have other biological functions; for more information, see the separate articles on Vitamin C and Vitamin E. Several trials have investigated whether supplementation with vitamins C and E improves pregnancy-associated hypertension or preeclampsia, but evidence supporting such an effect is largely lacking. An early placebo-controlled trial found that supplementation with 1,000 mg/day of vitamin C and 400 mg of vitamin E (*RRR*-α-tocopherol) was associated with a 61% reduction in the incidence of preeclampsia in women at increased risk for the condition (80). However, more recent randomized controlled trials have not found supplementation at these dosages to be effective in preventing preeclampsia in high- or low-risk women (81-84). Nevertheless, adequate intake of antioxidant vitamins is important throughout pregnancy. According to data from the US National Health and Nutrition Examination Survey (NHANES), 42%-46% and 85%-94% of US adults do not meet the estimated average requirement (EAR) for vitamin C and vitamin E, respectively (85). The Linus Pauling Institute's recommends that adults, including pregnant women, reach daily intakes of at least 400 mg of vitamin C and 15 mg (22.5 IU) of vitamin E.

Vitamin D

In 2010, the FNB of the Institute of Medicine set the RDA for vitamin D at 15 µg (600 IU)/day for all pregnant women (86). The FNB based this recommendation on a limited number of studies using bone health as the only indicator, assuming minimal sun exposure. Vitamin D, however, has a number of other roles in disease prevention and health (see the article on Vitamin D), and several vitamin D researchers believe that vitamin D requirements for adults, including pregnant women, are higher than the current RDA (87-91). Moreover, a number of studies indicate that vitamin D deficiency and insufficiency are quite common among pregnant women (92-101).

Low vitamin D status in pregnancy has been associated with an increased risk of adverse outcomes for both the mother and the infant. For pregnant women, vitamin D deficiency (serum 25-hydroxyvitamin D less than 50 nmol/L [20 ng/mL]) has been associated with an increased risk of preeclampsia and gestational diabetes (102, 103). For infants, low maternal vitamin D status has been associated with an increased risk of preterm birth (birth before 37 weeks of gestation) and low birth weight (a newborn weighing less than 2,500 grams) (104-106). A pooled analysis of 15 randomized controlled trials concluded that vitamin D supplementation raises serum 25-hydroxyvitamin D during pregnancy and may reduce the risk of preeclampsia, low birth weight, and preterm birth; notably, combined supplementation of vitamin D and calcium may increase the risk of preterm birth (107).

Vitamin D is found in very few foods, and prenatal supplements often contain only 10 µg (400 IU) of vitamin D. Sunlight exposure is the main source of the vitamin: vitamin D_3 (cholecalciferol) is synthesized in skin cells following exposure to ultraviolet-B radiation. However, the contribution of sun exposure to vitamin D status depends on many factors, including latitude, skin color, amount of skin exposed, duration of exposure, and the use of sunscreens, which effectively block skin production of vitamin D. Thus, vitamin D supplementation throughout pregnancy is likely needed to achieve body concentrations thought to benefit fetal and maternal health. The Linus Pauling Institute recommends that generally healthy adults, including pregnant women, take 2,000 IU (50 µg) of supplemental vitamin D daily. Because sun exposure, diet, skin color, and obesity have variable, substantial impact on body vitamin D concentrations, measuring serum concentrations of 25-hydroxyvitamin D — the clinical indicator of vitamin D status — is important. The Linus Pauling Institute recommends aiming for a serum 25-hydroxyvitamin D level of at least 75 nmol/L (30 ng/mL).

Vitamin K

The adequate intake (AI) for vitamin K (90 µg/day for women aged 19-50 years and 75 µg/day for those aged 14-18 years) is not increased during pregnancy, and a tolerable upper intake level (UL) has not been set for vitamin K. However, if taken during pregnancy, a number of drugs, including warfarin, rifampin, isoniazid, and anticonvulsants, may increase the risk of neonatal vitamin K deficiency and hemorrhagic disease of the newborn (108).

Placental transfer of vitamin K is low, thus all infants are born with low concentrations of vitamin K. A small proportion of newborns (0.25 to 1.1%) does not have enough vitamin K to make their blood clot and may develop vitamin K deficiency bleeding (VKDB) (109). There are three categories of VKDB depending on the age of onset: early (0-24 hours), classic (one to seven days), and late (two to 12 weeks) (110-112). Early VKDB is seen mainly in infants of mothers taking drugs that inhibit vitamin K, as listed above. Classic VKDB is more common and presents as bruising, gastrointestinal blood loss, or bleeding from the umbilicus, skin, or site of circumcision. Late VKDB is particularly concerning as it can lead to life-threatening intracranial bleeding. Randomized controlled trials have demonstrated that prophylactic intramuscular (IM) vitamin K injection of the newborn raises plasma vitamin K concentration, reduces PIVKA II (a marker of vitamin K deficiency), improves prothrombin time, and decreases the risk of classic VKDB compared to placebo (reviewed in 111). Administration of multiple oral doses of vitamin K can reduce PIVKA II concentrations and raise plasma vitamin K concentration but is associated with an increased incidence of late VKDB (109, 111, 113). The American Academy of Pediatrics and several international professional organizations recommend that all babies receive 0.5 to 1.0 mg intramuscular vitamin K_1 injection shortly after birth to prevent VKDB (109, 110, 114).

Minerals

Calcium

Although 200 to 250 mg/day of calcium is transferred to the fetus, primarily in the last trimester, dietary intake requirements of calcium are not increased due to maternal physiological adaptations. In particular, the efficiency of intestinal calcium absorption doubles during pregnancy, and the mineral can also be transiently mobilized from maternal stores (i.e., the skeleton) to support fetal needs for calcium. Permanent demineralization of bone during pregnancy has not been observed (86, 115). Moreover, there is no evidence from randomized controlled trials that calcium supplementation during pregnancy confers any benefit to maternal or fetal bone health (116, 117). The RDA is 1,300 mg/day for women aged 14-18 years and 1,000 mg/day for women aged 19-50 years.

Calcium intake during pregnancy, however, may influence the risk for pregnancy-induced hypertension (PIH). PIH, which occurs in 10% of pregnancies and is a major health risk for pregnant women and the fetus, is a term that includes gestational hypertension, preeclampsia, and eclampsia. Gestational hypertension is defined as an abnormally high blood pressure that usually develops after the 20th week of pregnancy. In addition to gestational hypertension, preeclampsia includes the development of edema (severe swelling) and proteinuria (protein in the urine). Preeclampsia may progress to eclampsia in which life-threatening convulsions and coma may occur (118). Risk factors for PIH include first pregnancies, multiple gestations (e.g., twins or triplets), chronic high blood pressure, diabetes, and some autoimmune diseases. Although the cause of PIH is not entirely understood, calcium metabolism appears to play a role. Low calcium intake during pregnancy may: (1) stimulate parathyroid hormone release, thereby increasing intracellular calcium and vascular smooth muscle contractility; and/or (2) stimulate renin release, leading to vasoconstriction and retention of sodium and fluid (119). Data from observational studies suggest an inverse relationship between dietary calcium intake and the incidence of PIH (120). Additionally, a recent systematic review of randomized, placebo-controlled trials (RCTs) reported that calcium supplementation during pregnancy (≥1,000 mg/day) was associated with a 35% lower risk of high blood pressure and a 55% lower risk of preeclampsia; the risk reduction for preeclampsia was even stronger for women considered to be at high risk for the condition (78% lower risk compared to placebo) and women with low dietary intake of calcium (64% lower risk compared to placebo) (121). This analysis also found that calcium supplementation lowered the risk of preterm birth by 24%, but no significant effect of calcium supplementation was found regarding the risk of stillbirth, admission to neonatal intensive care unit, or neonatal mortality before hospital discharge. Of four RCTs that monitored maternal death or serious morbidity, one RCT (122) reported a 20% reduced risk for the "severe maternal morbidity and mortality index" (a summary indicator defined as the presence of at least one of the following outcomes: maternal admission to intensive care or any special care unit, eclampsia, severe preeclampsia, placental abruption, HELLP syndrome [hemolysis, elevated liver enzymes, and low platelet count], renal failure, or death) with calcium supplementation; no events occurred in the other three RCTs (121).

Chromium

Chromium is known to enhance the action of insulin; therefore, several studies have investigated the utility of chromium supplementation for the control of blood glucose concentrations in type 2 diabetes (see the article on Chromium). However, its use in gestational diabetes — a condition that affects 4.6%-9.2% of all pregnancies in the US (123) — has not been well studied. Gestational diabetes is a glucose intolerance that usually appears in the second or third trimester of pregnancy; blood glucose concentrations must be tightly controlled to prevent adverse effects on the developing fetus and other pregnancy complications. After delivery, glucose tolerance generally reverts to normal, but women are at a heightened risk of developing type 2 diabetes (124). In fact, a recent systematic review and meta-analysis found that the risk of developing type 2 diabetes in women diagnosed with gestational diabetes is more than 7-fold higher than women not diagnosed with gestational diabetes (125). Gestational diabetes is also considered a risk factor for cardiovascular disease (124). Two observational studies found that serum concentrations of chromium in pregnant women were not associated with glucose intolerance or gestational diabetes (126, 127), although serum chromium concentrations may not necessarily reflect tissue chromium concentrations. An eight-week placebo-controlled trial in 24 women with gestational diabetes found that supplementation in the form of chromium picolinate (4 µg/day of chromium per kilogram of body weight) was associated with lower fasting blood glucose and insulin concentrations (128). However, it is important to note that insulin therapy was still required to normalize the severely elevated blood glucose concentrations. Thus, more research, especially from randomized controlled trials, is needed to determine whether chromium supplementation has any utility in the treatment of gestational diabetes.

Iodine

Iodine requirements are increased by more than 45% during pregnancy: the RDA for pregnant women is 220 µg/day compared to 150 µg/day for women who are not pregnant. Adequate intake of this mineral is needed for maternal thyroid hormone production, and thyroid hormone is needed for myelination of the central nervous system and is thus essential for normal fetal brain development (129). If iodine deficiency leads to inadequate production of thyroid hormone during pregnancy, irreversible brain damage in the fetus may occur (130). Severe maternal iodine deficiency has also been associated with increased incidence of miscarriage, stillbirth, and birth defects (131).

One of the most devastating effects of severe maternal iodine deficiency is congenital hypothyroidism (132). A severe form of congenital hypothyroidism may lead to a condition that is sometimes referred to as cretinism and result in irreversible mental retardation. Cretinism occurs in two forms, neurologic and myxedematous, although there is considerable overlap between them. The neurologic form is characterized by mental and physical retardation and deafness; it results from maternal iodine deficiency that affects the fetus before its own thyroid is functional. The myxedematous or hypothyroid form is characterized by short stature and mental retardation (133). Severe maternal iodine deficiency has also been linked to neurocognitive deficits in the offspring (134). In severely iodine-deficient pregnant women, iodine supplementation effectively reduces rates of cretinism, and improves offspring cognitive function and survival (reviewed in 135). The timing of iodine supplementation appears to be important: supplementation should be initiated prior to conception and early in pregnancy (before the 10th week of gestation) in order to see beneficial effects on offspring neurocognitive outcomes (135).

Even mild forms of maternal iodine deficiency may have adverse effects on cognitive development in the offspring (136), though this outcome is less well studied. Randomized controlled trials conducted in moderately iodine deficient pregnant women demonstrate that iodine supplementation increases thyroid gland volume but has no effect on thyroid hormone concentrations compared to placebo (reviewed in 130 and 135). The extent to which supplementation in moderately iodine deficient pregnant women affects neurocognitive outcomes in their offspring is currently under investigation (137).

Iodine deficiency is now accepted as the most common cause of preventable brain damage in the world (131). Thus, adequate intake of the mineral throughout pregnancy is critical. A daily supplement providing 150 µg of iodine, as recommended by the American Thyroid Association (138), will help to ensure that US pregnant women consume sufficient iodine. However, it is important to note that several prenatal supplements and some multivitamin/mineral supplements on the market in the US do not contain iodine (139), presumably because manufacturers assume that women receive sufficient iodine through iodized salt and other food sources. For more information on iodine and iodine deficiency disorders, see the article on Iodine.

Iron

Iron requirements are significantly increased during pregnancy: the RDA is 27 mg/day for pregnant women of all ages compared to 15 to 18 mg/day for nonpregnant women. Many women have dietary iron intakes below current recommendations. National surveys in the US indicate that the average dietary iron intake is about 12 mg/day in nonpregnant women and 15 mg/day in pregnant women (140). Iron is needed for a number of biological functions (see the article on Iron), but during pregnancy, the mineral is generally needed to support growth and development of the fetus and placenta and to meet the increased demand for red blood cells to transport oxygen. Intestinal absorption of dietary iron increases during the second and third trimesters to accommodate for expansion of red cell mass (140). Maternal blood volume expands by almost 50% during pregnancy, which results in a hemodilution of red blood cells (141).

Despite maternal physiologic changes that enhance iron absorption, many women develop iron-deficiency or iron-deficiency anemia during pregnancy. The World Health Organization estimates that the worldwide prevalence of anemia among pregnant women is 42%; the prevalence of anemia is much higher in less developed nations compared with industrialized nations, with almost 90% of these anemic women living in Africa or Asia (142). In pregnant women in the US, the prevalence of iron deficiency is 18%, and the prevalence of iron-deficiency anemia is 5% (143). Anemias can be caused by deficiencies in other micronutrients, such as folate or vitamin B_{12}, but iron deficiency is the primary cause of anemia during pregnancy (1). Severe iron-deficiency anemia has been associated with an increased risk of maternal death (142) and with an increased risk of low birth weight infants (<2,500 grams), premature delivery, and perinatal mortality (144).

Two 2015 systematic reviews evaluated the effect of routine iron supplementation compared to placebo or no treatment on maternal and birth outcomes (145, 146). Both reviews found that routine supplementation with iron improved maternal iron status and decreased the risk of iron deficiency and iron-deficiency anemia at term. There is some indication that maternal iron supplementation could improve birth outcomes (namely preterm birth and low birth weight) in developing countries, but the evidence was deemed of low quality (146). Women taking higher doses of iron (≥60 mg/day) tended to have abnormally high hemoglobin values at term and were more likely to report side effects (146); side effects of high-dose iron supplements include nausea, constipation, vomiting, and diarrhea.

Iron status of the woman at the time of conception is important for a healthy pregnancy, to avoid postpartum anemia, and to provide the breast-feeding infant with sufficient iron stores until six months of age, when complementary feeding is recommended. Because of the increased demands for the mineral during the second and third trimesters of pregnancy, iron supplementation (30 mg/day) is usually recommended beginning at 12 weeks' gestation (147). Absorption of nonheme iron, which is the form of iron found in supplements, is affected by a number of enhancers (e.g., vitamin C) as well as inhibitors (e.g., polyphenols found in tea and coffee). In general, iron supplements are better absorbed on an empty stomach. High doses of iron supplements taken together with zinc supplements on an empty stomach can inhibit the absorption of zinc (140, 148); supplemental iron at 38 to 65 mg/day of elemental iron may decrease zinc absorption (149). For more information about dietary and supplemental sources of iron, as well as the side effects and safety of iron, see the article on Iron.

Magnesium

The mineral magnesium plays a number of important roles in the structure and the function of the human body (see the article on Magnesium), and adequate intake of the mineral is needed for normal embryonic and fetal development. National dietary surveys indicate that magnesium insufficiency is relatively common in the US, with 56% of American adults not meeting the EAR — the nutrient intake value that is estimated to meet the requirement of half of the healthy individuals in a particular life stage and gender group (150). Good sources of magnesium include green leafy vegetables, whole grains, and nuts (see the article on Magnesium). Several multivitamin/mineral and prenatal supplements do not contain magnesium or contain no more than 100 mg of magnesium.

Preeclampsia-eclampsia is a disease that is unique to pregnancy and may occur anytime after 20 weeks' gestation. Preeclampsia is defined as the presence of elevated blood pressure and protein in the urine; severe swelling (edema) may also be present. Eclampsia occurs with the addition of seizures to these symptoms. Approximately 5%-8% of women with preeclampsia go on to develop eclampsia in developing countries, which is a significant cause of maternal death (84).

A 2014 pooled analysis of randomized controlled trials concluded that oral magnesium supplementation during pregnancy has no significant effect on perinatal mortality, small-for-gestational age, or the risk of preeclampsia (151). Intravenous administration of high-dose magnesium sulfate has been the treatment of choice for preventing eclamptic seizures that may occur in association with preeclampsia-eclampsia in late pregnancy or during labor (152-154). Magnesium is believed to relieve cerebral blood vessel spasm and promote peripheral vasodilation, thereby increasing blood flow to the brain (155-157).

Zinc

The RDA for zinc is increased during pregnancy (from 8 mg/day-9 mg/day to 11 mg/day-12 mg/day), and pregnant women, especially teenagers, are at increased risk of zinc deficiency. It has been estimated that 82% of pregnant women in the world may have inadequate intake of dietary zinc (158), leading to poor nutritional status of the mineral. Poor nutritional status of zinc during pregnancy has been associated with a number of adverse outcomes, including low birth weight (<2,500 grams), premature delivery, labor and delivery complications, and congenital anomalies (159). However, the results of maternal zinc supplementation trials in the US and developing countries have been mixed (160). A 2014 systematic review of 16 randomized controlled trials found that zinc supplementation during pregnancy was associated with a 14% reduction in premature deliveries; the lower incidence of preterm births was observed mainly in low-income women (161). This analysis, however, did not find zinc supplementation to benefit other indicators of maternal or infant health.

It is important to note that supplemental levels of iron (38 to 65 mg/day of elemental iron), but not dietary levels of iron, may decrease zinc absorption (149). Because iron supplementation is often recommended during pregnancy (see Iron above), pregnant women who take more than 60 mg/day of elemental iron may want to take a prenatal or multivitamin-mineral supplement that also includes zinc (162).

Other Nutrients

Choline

Choline can be synthesized by the body in small amounts, but dietary intake is needed to maintain health (163). Choline is essential for embryonic and fetal brain development, liver function, and placental function (164). The choline metabolite betaine is a source of methyl (CH_3) groups required for methylation reactions; DNA methylation that occurs during embryonic and fetal development modulates gene expression, cell differentiation, and the formation of organs (77). A mother delivers large amounts of choline to the fetus across the placenta and to the infant via breast milk, placing an increased demand on maternal stores of choline during pregnancy and lactation (164). The induction of *de novo* choline synthesis by the high levels of estrogen during pregnancy helps to meet this increased demand (165). Additionally, pregnant women are encouraged to consume choline-rich foods, such as eggs, meat, and seafood (for dietary sources, see the article on Choline). The adequate intake (AI) for pregnant women is 450 mg/day of choline, slightly higher than the 425 mg/day recommended for nonpregnant women (166).

Case-control studies have reported mixed results regarding the relationship between dietary choline intake or blood choline concentration and the risk of neural tube defects (NTDs). One case-control study reported a lower risk of having an NTD-affected pregnancy in those with the highest intake of betaine and choline combined (167), while two other studies found no association between maternal choline intake and NTD risk (168, 169). Similarly, one case-control study found low serum choline concentration was associated with a higher risk of NTDs (170), while another study found no such association (171). Additionally, it is not known if supplementation with choline or betaine, like supplementation with folic acid (see Folate above), will lower the incidence of NTDs. More research is needed to determine whether choline is involved in the etiology of NTDs.

Maternal intake of choline during pregnancy could possibly affect cognitive abilities of the offspring. Choline supplementation in pregnant rats, as well as rat pups during the first month of life, leads to improved performance in spatial memory tests months after choline supplementation has been discontinued (172). A review by McCann et al. discusses the experimental evidence from rodent studies regarding the availability of choline during prenatal development and cognitive function in the offspring (173). It is not clear whether findings in rodent studies are applicable to humans. One randomized controlled trial demonstrated that choline supplementation (750 mg/day of choline in the form of phosphatidylcholine administered from week 18 of gestation through 90 days postpartum) in pregnant women consuming a moderate-choline diet (approximately 360 mg/day) was safe but did not enhance infant cognitive function at 10 or 12 months of age (174).

Finally, choline is important for homocysteine metabolism during pregnancy. Methyl groups derived from choline may be used to convert homocysteine to methionine. Elevated blood homocysteine concentrations have been associated with increased risk of preeclampsia, premature delivery, low placental weight, low birth weight (<2,500 grams), very low birth weight (<1,500 grams), small for gestational age, NTDs, and stillbirth (48-50).

Essential fatty acids

Although not micronutrients, certain fatty acids are required in the maternal diet during pregnancy and lactation; the US Institute of Medicine's adequate intake (AI) recommendations for omega-3 and omega-6 fatty acids during pregnancy and lactation are listed in the separate article on Essential Fatty Acids. For more information on the importance of omega-3 fatty acids during these life stages, see two sections in the separate article on essential fatty acids: Visual and neurological development and Pregnancy and lactation. Information about environmental contaminants in fish and supplements is included in the sections, Contaminants in fish and Contaminants in supplements.

Safety in Pregnancy

Table 2. UL for Micronutrients During Pregnancy

Micronutrient	Age	UL
Biotin	14-50 years	ND[a]
Folate	14-18 years	800 μg/day[b]
	19-50 years	1,000 μg/day[b]
Niacin	14-18 years	30 mg/day[b]
	19-50 years	35 mg/day[b]
Pantothenic Acid	14-50 years	ND
Riboflavin	14-50 years	ND
Thiamin	14-50 years	ND
Vitamin A	14-18 years	2,800 μg (9,333 IU)/day[c]
	19-50 years	3,000 μg (10,000 IU)/day[c]
Vitamin B_6	14-18 years	80 mg/day
Vitamin B_6	19-50 years	100 mg/day
Vitamin B_{12}	14-50 years	ND
Vitamin C	14-18 years	1,800 mg/day
	19-50 years	2,000 mg/day
Vitamin D	14-50 years	100 μg (4,000 IU)/day
Vitamin E	14-18 years	800 mg (1,200 IU)/day[d]
	19-50 years	1,000 mg (1,500 IU)/day[d]
Vitamin K	14-50 years	ND
Calcium	14-18 years	3,000 mg/day
	19-50 years	2,500 mg/day
Chromium	14-50 years	ND
Copper	14-18 years	8 mg/day
	19-50 years	10 mg/day
Fluoride	14-50 years	10 mg/day
Iodine	14-18 years	900 μg/day
	19-50 years	1,100 μg/day
Iron	14-50 years	45 mg/day
Magnesium	14-50 years	350 mg/day[e]
Manganese	14-18 years	9 mg/day
	19-50 years	11 mg/day
Molybdenum	14-18 years	1,700 μg/day
	19-50 years	2,000 μg/day
Phosphorus	14-50 years	3,500 mg/day
Potassium	14-50 years	ND
Selenium	14-50 years	400 μg/day
Sodium	14-50 years	ND
Zinc	14-18 years	34 mg/day
	19-50 years	40 mg/day
Choline[f]	14-18 years	3,000 mg/day
	19-50 years	3,500 mg/day

[a] ND, not determinable because data are lacking
[b] Applies to the synthetic form in fortified foods and supplements
[c] Applies to only preformed vitamin A (retinol)
[d] Applies to any form of supplemental α-tocopherol
[e] Applies only to the supplemental form
[f] Considered an essential nutrient, although not strictly a micronutrient

Maternal Micronutrient Requirements During Lactation

Breast-feeding confers health benefits to the child, as well as the mother (175). Breast milk is the ideal source of nutrition for the infant and also contains a number of bioactive compounds important in immunity, such as antibodies, cytokines, antimicrobial agents, and oligosaccharides (176). The American Academy of Pediatrics recommends exclusive breast-feeding for the first six months of infancy, followed by continued breast-feeding as complementary foods are introduced, with continuation of breast-feeding until 12 months postpartum or longer as mutually desired by the mother and child (177). The World Health Organization recommends exclusive breast-feeding for the first six months of life and continued breast-feeding, with complementary feeding, up to two years or more postpartum (178). There are, however, a few exceptions when breast-feeding is contraindicated, including those listed on the CDC website.

Lactation is extremely energy expensive (exceeding pre-pregnancy demands by approximately 500 kcal/day), and macronutrient requirements for breast-feeding women are even higher than during pregnancy (175). Likewise, the intake recommendations (RDA or AI) for most micronutrients, which are based on amounts secreted in breast milk, are higher for lactating women compared to pregnant women (see **Table 3**). One notable exception is the RDA for iron, which is significantly lower during lactation (9 to 10 mg/day) compared to pregnancy (27 mg/day) (140). Breast milk is considered to be low in iron; however, the iron content of breast milk is not influenced by changes in maternal iron status, such as through maternal supplementation (59). The RDA for folate is also lower during lactation compared with pregnancy. Dietary intake recommendations for calcium remain unchanged for lactating women compared to recommendations for nonlactating women, and calcium content in breast milk does not reflect maternal intake of the mineral. Adequate calcium is maintained in breast milk because of maternal physiological changes that involve transient bone resorption; increased maternal intake of calcium through diet and supplementation does not prevent maternal bone demineralization, and studies have shown that maternal bone mineral content is restored upon weaning (179).

In general, the amounts of water-soluble vitamins (B vitamins and vitamin C) in breast milk reflect maternal intake from diet and/or supplements. Thus, meeting daily intake recommendations for these micronutrients is important for the health of the child. Maternal vitamin deficiencies can negatively affect infant growth and development; for instance, vitamin B_{12} deficiency during infancy can impair brain development and cause neurological problems (180). Vitamin B_{12} deficiency has been documented in nursing infants of mothers who have untreated pernicious anemia and also in women who are strict vegetarians (vegans) (181). Vitamin B_{12} is found only in foods of animal origin and fortified foods, and lactating women who follow vegetarian diets should take supplemental vitamin B_{12}. Vitamin B_{12} deficiency that results from pernicious anemia can easily be corrected with high-dose daily supplementation or with monthly intramuscular injections of the vitamin (see the article on Vitamin B_{12}). However, there has been relatively little research on the effect of oral vitamin B_{12} supplementation in lactating women, and it has been suggested that supplementation during lactation may be too late to restore adequate milk concentrations and infant status (182). Supplementation during pregnancy may more effectively improve infant vitamin B_{12} status. For instance, oral daily vitamin B_{12} supplementation (50 μg/day) administered from <14 weeks gestation through 6 weeks postpartum significantly increased maternal plasma and breast milk concentrations of vitamin B_{12} and improved infant vitamin B_{12} status (183). The concentrations of other water-soluble vitamins in breast milk, including thiamin, riboflavin, and vitamin B_6, are also strongly dependent on maternal intake of these vitamins (59, 182). Likewise, vitamin C concentration in human milk varies with the vitamin C status of the mother. Vitamin C supplementation can moderately increase concentrations of the vitamin in breast milk, especially in lactating women with poor vitamin C status (184), and maternal intakes of 100 mg/day maximize the amount of vitamin C in breast milk (185).

Compared to water-soluble vitamins, the concentrations of fat-soluble vitamins (vitamins A, D, E, and K) in breast milk are less correlated with maternal dietary intake. The RDA for vitamin A during lactation is 1,200 to 1,300 μg/day (4,000 to 4,333 IU/day). At such levels of maternal intake, breast milk is a good source of vitamin A and provides the infant with a sufficient amount of the vitamin (186). In contrast, breast milk is considered to be low in vitamins D and K. Vitamin D concentrations in human milk are dependent on maternal vitamin D status, which is determined by the woman's sun exposure and dietary and supplemental intake. Vitamin D concentrations are low in breast milk, presumably because many women have insufficient vitamin D status. Vitamin D supplementation during lactation has been shown to improve vitamin D status in the woman and the infant (187). The RDA for lactating women is 600 IU/day of vitamin D, but intake at this level in the absence of sun exposure likely results in insufficient amounts for the infant. To prevent vitamin D deficiency and rickets in infants, the American Academy of Pediatrics recommends that all breast-fed and partially breast-fed infants be given a vitamin D supplement of 400 IU/day (177). Liquid vitamin D supplements are commercially available for infant supplementation. The Linus Pauling Institute recommends that all adults take 2,000 IU/day of supplemental vitamin D and aim for a serum 25-hydroxyvitamin D level of at least 75 nmol/L (30 ng/mL). Human milk is also relatively low in vitamin K. Thus, exclusively breast-fed newborns are at increased risk for vitamin K deficiency. In general, newborns have low vitamin K status for the following reasons: (1) vitamin K is not easily transported across the placental barrier; (2) the newborn's intestines are not yet colonized with bacteria that synthesize vitamin K; and (3) the vitamin K cycle may not be fully functional in newborns, especially premature infants (188). Vitamin K deficiency in newborns may result in a bleeding disorder called vitamin K deficiency bleeding (VKDB). Because VKDB is life-threatening and easily prevented, the American Academy of Pediatrics and a number of similar international organizations recommend that an injection of phylloquinone (vitamin K_1) be administered to all newborns shortly after birth (110, 114, 177). Additionally, the vitamin E content in breast milk varies with maternal diet and vitamin E supplement use (184, 186). The RDA for vitamin E during lactation is 19 mg/day (28.5 IU/day) of α-tocopherol. National surveys indicate that more than 90% of US adults have daily vitamin E intakes below 12 mg (18 IU) (85).

Maternal dietary intake recommendations for the 14 essential minerals during lactation are shown in **Table 3**. The content of minerals in breast milk does not correlate well with maternal intake or status, except for iodine and selenium (1, 176). Iodine requirements are increased during lactation: breast-feeding women require 290 μg/day of iodine compared to 220 μg/day for pregnant women and 150 μg/day for nonpregnant, nonlactating women (129). Iodine-deficient women who are breast-feeding may not be able to provide sufficient iodine to their infants who are particularly vulnerable to the effects of iodine deficiency (see the article on Iodine). A daily supplement providing 150 μg of iodine, as recommended by the American Thyroid Association (138), will help to ensure that US breast-feeding women consume sufficient iodine during these critical periods. Additionally, the RDA for selenium is slightly higher for lactating women (from 60 to 70 μg/day), and selenium content in breast milk reflects maternal intake (189).

Table 3. RDA for Maternal Micronutrients During Lactation

Micronutrient	Age	RDA
Biotin	14-50 years	35 μg/day (AI)
Folate	14-50 years	500 μg/day[a]
Niacin	14-50 years	17 mg/day[b]
Pantothenic Acid	14-50 years	7 mg/day (AI)
Riboflavin	14-50 years	1.6 mg/day
Thiamin	14-50 years	1.4 mg/day
Vitamin A	14-18 years	1,200 μg (4,000 IU)/day[c]
	19-50 years	1,300 μg (4,333 IU)/day[c]
Vitamin B_6	14-50 years	2.0 mg/day
Vitamin B_{12}	14-50 years	2.8 μg/day
Vitamin C	14-18 years	115 mg/day
	19-50 years	120 mg/day
Vitamin D	14-50 years	15 μg (600 IU)/day
Vitamin E	14-50 years	19 mg (28.5 IU)/day[d]
Vitamin K	14-18 years	75 μg/day (AI)
	19-50 years	90 μg/day (AI)
Calcium	14-18 years	1,300 mg/day
	19-50 years	1,000 mg/day
Chromium	14-18 years	44 μg/day (AI)
	19-50 years	45 μg/day (AI)
Copper	14-50 years	1.3 mg/day
Fluoride	14-50 years	3 mg/day (AI)
Iodine	14-50 years	290 μg/day
Iron	14-18 years	10 mg/day
	19-50 years	9 mg/day
Magnesium	14-18 years	360 mg/day
	19-30 years	310 mg/day
	31-50 years	320 mg/day
Manganese	14-50 years	2.6 mg/day (AI)
Molybdenum	14-50 years	50 μg/day
Phosphorus	14-18 years	1,250 mg/day
	19-50 years	700 mg/day
Potassium	14-18 years	2,500 mg/day (AI)
	19-50 years	2,800 mg/day (AI)
Selenium	14-50 years	70 μg/day
Sodium	14-50 years	1,500 mg/day (AI)
Zinc	14-18 years	13 mg/day
	19-50 years	12 mg/day
Choline[e]	14-50 years	550 mg/day (AI)

AI, adequate intake
[a] Dietary Folate Equivalents
[b] NE, niacin equivalent: 1 mg NE = 60 mg tryptophan = 1 mg niacin
[c] Retinol Activity Equivalents
[d] α-Tocopherol
[e] Considered an essential nutrient, although not strictly a micronutrient

Safety in Lactation

The tolerable upper intake level (UL) for each micronutrient is shown in the **Table 4**. The UL, established by the Food and Nutrition Board of the Institute of Medicine, is the highest level of daily intake that is likely to pose no risk of adverse health effects in almost all individuals.

Table 4. UL for Maternal Micronutrients During Lactation

Micronutrient	Age	UL
Biotin	14-50 years	ND[a]
Folate	14-18 years	800 μg/day[b]
	19-50 years	1,000 μg/day[b]
Niacin	14-18 years	30 mg/day[b]
	19-50 years	35 mg/day[b]
Pantothenic Acid	14-50 years	ND
Riboflavin	14-50 years	ND
Thiamin	14-50 years	ND
Vitamin A	14-18 years	2,800 μg (9,333 IU)/day[c]
	19-50 years	3,000 μg (10,000 IU)/day[c]
Vitamin B_6	14-18 years	80 mg/day
Vitamin B_6	19-50 years	100 mg/day
Vitamin B_{12}	14-50 years	ND
Vitamin C	14-18 years	1,800 mg/day
	19-50 years	2,000 mg/day
Vitamin D	14-50 years	100 μg (4,000 IU)/day
Vitamin E	14-18 years	800 mg (1,200 IU)/day[d]
	19-50 years	1,000 mg (1,500 IU)/day[d]
Vitamin K	14-50 years	ND
Calcium	14-18 years	3,000 mg/day
	19-50 years	2,500 mg/day
Chromium	14-50 years	ND
Copper	14-18 years	8 mg/day
	19-50 years	10 mg/day
Fluoride	14-50 years	10 mg/day
Iodine	14-18 years	900 μg/day
	19-50 years	1,100 μg/day
Iron	14-50 years	45 mg/day
Magnesium	14-50 years	350 mg/day[e]
Manganese	14-18 years	9 mg/day
	19-50 years	11 mg/day
Molybdenum	14-18 years	1,700 μg/day
	19-50 years	2,000 μg/day
Phosphorus	14-50 years	4,000 mg/day
Potassium	14-50 years	ND
Selenium	14-50 years	400 μg/day
Sodium	14-50 years	ND
Zinc	14-18 years	34 mg/day
	19-50 years	40 mg/day
Choline[f]	14-18 years	3,000 mg/day
	19-50 years	3,500 mg/day

[a] ND, not determinable because data are lacking
[b] Applies to the synthetic form in fortified foods and supplements
[c] Applies to only preformed vitamin A (retinol)
[d] Applies to any form of supplemental α-tocopherol
[e] Applies only to the supplemental form
[f] Considered an essential nutrient, although not strictly a micronutrient

Micronutrients for Older Adults

Introduction

Listed below are vitamin and mineral dietary intake recommendations for individuals over the age of 50 years. For each micronutrient, the Food and Nutrition Board of the Institute of Medicine establishes a recommended dietary allowance (RDA) or adequate intake (AI). Generally, the Linus Pauling Institute supports the recommendations of the Food and Nutrition Board, but any discrepancies in dietary recommendations are listed in the rightmost column of the table. Additionally, more information on the Linus Pauling Institute recommendation for a specific micronutrient can be found by clicking on the name of the micronutrient of interest.

Table 1. Micronutrient Requirements for Older Adults (>50 years)

	Food and Nutrition Board Recommendations (RDA except where otherwise noted)		Linus Pauling Institute Recommendation
Micronutrient	**Men**	**Women**	
Vitamins			
Biotin	30 µg/day (AI)	30 µg/day (AI)	
Folate	400 µg/day	400 µg/day	
Niacin	16 mg NE*/day	14 mg NE/day	
Pantothenic acid	5 mg/day (AI)	5 mg/day (AI)	
Riboflavin	1.3 mg/day	1.1 mg/day	
Thiamin	1.2 mg/day	1.1 mg/day	
Vitamin A	900 µg (3,000 IU)/day	700 µg (2,333 IU)/day	
Vitamin B_6	1.7 mg/day	1.5 mg/day	2.0 mg/day
Vitamin B_{12}	2.4 µg/day#	2.4 µg/day#	100-400 µg/day of crystalline vitamin B_{12}
Vitamin C	90 mg/day	75 mg/day	≥400 mg/day
Vitamin D (51-70 years)	15 µg (600 IU)/day	15 µg (600 IU)/day	2,000 IU/day from supplements
Vitamin D (>70 years)	20 µg (800 IU)/day	20 µg (800 IU)/day	2,000 IU/day from supplements
Vitamin E	15 mg (22.5 IU)/day	15 mg (22.5 IU)/day	
Vitamin K	120 µg/day (AI)	90 µg/day (AI)	
Minerals			
Calcium (51-70 years)	1,000 mg/day	1,200 mg/day	
Calcium (>70 years)	1,200 mg/day	1,200 mg/day	
Chromium	30 µg/day (AI)	20 µg/day (AI)	
Copper	900 µg/day	900 µg/day	
Fluoride	4 mg/day (AI)	3 mg/day (AI)	
Iodine	150 µg/day	150 µg/day	
Iron	8 mg/day	8 mg/day	No supplement
Magnesium	420 mg/day	320 mg/day	No supplement providing >350 mg/day
Manganese	2.3 mg/day (AI)	1.8 mg/day (AI)	
Molybdenum	45 µg/day	45 µg/day	
Phosphorus	700 mg/day	700 mg/day	
Potassium	3.4 g/day (AI)	2.6 g/day (AI)	
Selenium	55 µg/day	55 µg/day	
Sodium	1.5 g/day (AI)	1.5 g/day (AI)	
Zinc	11 mg/day	8 mg/day	

*NE, niacin equivalent: 1 mg NE = 60 mg of tryptophan = 1 mg niacin
#Vitamin B_{12} intake should be from supplements or fortified foods due to the age-related increase in malabsorption
Abbreviations: µg=microgram; mg=milligram; g=gram; IU=International Unit; RDA=Recommended Dietary Allowance; AI=Adequate Intake

Linus Pauling Institute Recommendations

Vitamins

Biotin

Presently, there is no indication that older adults have an increased requirement for biotin. If dietary biotin intake is not sufficient, a daily multivitamin/mineral supplement will generally provide an intake of at least 30 µg/day of biotin.

Folate

The Linus Pauling Institute recommends that adults take a 400 µg supplement of folic acid daily, in addition to folate and folic acid consumed in the diet. A daily multivitamin/mineral supplement, containing 100% of the Daily Value (DV) for folic acid provides 400 µg of folic acid. Even with a larger than average intake of folic acid from fortified food, it is unlikely that an individual's daily folic acid intake would regularly exceed the tolerable upper intake level (UL) of 1,000 µg/day established by the Food and Nutrition Board. The recommendation for 400 µg/day of supplemental folic acid as part of a daily multivitamin/mineral supplement, in addition to a folate-rich diet, is especially important for older adults because blood homocysteine levels tend to increase with age.

Niacin

Dietary surveys indicate that 15% to 25% of older adults do not consume enough niacin in their diets to meet the RDA (16 mg NE/day for men and 14 mg NE/day for women), and that dietary intake of niacin decreases between the ages of 60 and 90 years. Thus, it is advisable for older adults to supplement their dietary intake with a multivitamin/mineral supplement, which will generally provide at least 20 mg of niacin daily.

Pantothenic acid

Presently, there is little evidence that older adults differ in their intake or requirement for pantothenic acid. Most multivitamin/mineral supplements provide at least 5 mg/day of pantothenic acid. The Linus Pauling Institute supports the recommendation by the Food and Nutrition Board of 5 mg/day of pantothenic acid for older adults. A varied diet should provide enough pantothenic acid for most people. Following the Linus Pauling Institute recommendation to take a daily multivitamin/mineral supplement, containing 100% of the Daily Value (DV), will ensure an intake of at least 5 mg/day of pantothenic acid.

Riboflavin

Some experts in nutrition and aging feel that the RDA of riboflavin (1.3 mg/day for men and 1.1 mg/day for women) leaves little margin for error in people over 50 years of age (1, 2). A study of independently living people between 65 and 90 years of age found that almost 25% consumed less than the recommended riboflavin intake, and 10% had biochemical evidence of deficiency (3). Epidemiological studies of cataract prevalence indicate that riboflavin intakes of 1.6 to 2.2 mg/day may reduce the risk of developing age-related cataracts. Additionally, older people suffering from acute ischemic stroke were found to be deficient for riboflavin (4), and riboflavin deficiency has been linked to a higher risk of fracture in postmenopausal women with the *MTHFR* 677T variant (5). Individuals whose diets may not supply adequate riboflavin, especially those over 50 years of age, should consider taking a multivitamin/mineral supplement, which generally provides at least 1.7 mg/day of riboflavin.

Thiamin

Presently, there is no evidence that the requirement for thiamin is increased in older adults, but some studies have found inadequate dietary intake and thiamin insufficiency to be more common in elderly populations (2). Thus, it would be prudent for older adults to take a multivitamin/mineral supplement, which will generally provide at least 1.5 mg of thiamin/day.

Vitamin A

Presently, there is little evidence that the requirement for vitamin A in older adults differs from that of younger adults. Additionally, vitamin A toxicity may occur at lower doses in older adults than in younger adults. Further, data from observational studies suggested an inverse association between intakes of preformed vitamin A in excess of 1,500 µg RAE (5,000 IU)/day and risk of hip fracture in older people (see the Safety section in the article on Vitamin A). Yet, following the Linus Pauling Institute's recommendation to take a multivitamin/mineral supplement daily could supply as much as 5,000 IU/day of retinol, the amount that has been associated with adverse effects on bone health in older adults. For this reason, we recommend taking a multivitamin/mineral supplement that provides no more than 2,500 IU (750 µg) of preformed vitamin A (usually labeled vitamin A acetate or vitamin A palmitate) and no more than 2,500 IU of additional vitamin A as β-carotene. As for all age groups, high potency vitamin A supplements should not be used without medical supervision due to the risk of toxicity.

Vitamin B_6

Early metabolic studies have indicated that the requirement for vitamin B_6 in older adults is approximately 2 mg daily (6). Yet, the analysis of the US population survey (NHANES) 2003-2004 showed that adequate vitamin B_6 status and low homocysteine levels were associated with total vitamin B_6 intakes equal to and above 3 mg/day in people aged 65 years and older (7). The Linus Pauling Institute recommends that older adults take a multivitamin/mineral supplement, which provides at least 2.0 mg of vitamin B_6 daily.

Vitamin B_{12}

Because vitamin B_{12} malabsorption and vitamin B_{12} deficiency are more common in older adults, the Linus Pauling Institute recommends that adults older than 50 years take 100 to 400 µg/day of supplemental vitamin B_{12}.

Vitamin C

Although it is not yet known with certainty whether older adults have higher requirements for vitamin C, some older populations have been found to have vitamin C intakes considerably below the RDA of 75 and 90 mg/day for women and men, respectively. A vitamin C intake of at least 400 mg daily may be particularly important for older adults who are at higher risk for age-related chronic diseases. In addition, a meta-analysis of 36 publications examining the relationship between vitamin C intake and plasma concentrations of vitamin C concluded that older adults (aged 60-96 years) have considerably lower plasma levels of vitamin C following a certain intake of vitamin C compared with younger individuals (aged 15-65 years) (8), suggesting that older adults have higher vitamin C requirements. Pharmacokinetic studies in older adults have not yet been conducted, but evidence suggests that the efficiency of one of the molecular mechanisms for the cellular uptake of vitamin C declines with age (9). Because maximizing blood levels of vitamin C may be important in protection against oxidative damage to cells and biological molecules, a vitamin C intake of at least 400 mg daily is particularly important for older adults who are at higher risk for chronic diseases caused, in part, by oxidative damage, such as heart disease, stroke, certain cancers, and cataract.

Vitamin D

The Linus Pauling Institute recommends that generally healthy adults take 2,000 IU (50 µg) of supplemental vitamin D daily. Most multivitamins contain 400 IU of vitamin D, and single ingredient vitamin D supplements are available for additional supplementation. Sun exposure, diet, skin color, and obesity have variable, substantial impact on body vitamin D levels. To adjust for individual differences and ensure adequate body vitamin D status, the Linus Pauling Institute recommends aiming for a serum 25-hydroxyvitamin D level of at least 80 nmol/L (32 ng/mL). Numerous observational studies have found that serum 25-hydroxyvitamin D levels of 80 nmol/L (32 ng/mL) and above are associated with reduced risk of bone fractures, several cancers, multiple sclerosis, and type 1 (insulin-dependent) diabetes. Daily supplementation with 2,000 IU (50 µg) of vitamin D is especially important for older adults because aging is associated with a reduced capacity to synthesize vitamin D in the skin upon sun exposure.

Vitamin E

The RDA for adults of all ages is 15 mg (22.5 IU) per day of α-tocopherol. Notably, more than 90% of individuals aged two years and older in the US do not meet the daily requirement for vitamin E from food sources alone. Major sources of vitamin E in the American diet are vegetable oils, nuts, whole grains, and green leafy vegetables. LPI recommends that healthy older adults take a daily multivitamin/mineral supplement, which usually contains 30 IU of synthetic vitamin E, or 90% of the RDA.

Vitamin K

Older adults are at increased risk of osteoporosis and hip fracture. Because adequate intake of vitamin K is essential in maintaining bone health, the Linus Pauling Institute recommends that adults take a multivitamin/mineral supplement and consume at least one cup of dark green leafy vegetables daily. Although the AI for vitamin K was recently increased, it is not clear if it will be enough to optimize the γ-carboxylation of vitamin K-dependent proteins in bone (see the section on Osteoporosis in the article on vitamin K). Multivitamins generally contain 10 to 25 µg of vitamin K, whereas vitamin K or "bone" supplements may contain 100 to 120 µg of vitamin K. To consume the amount of vitamin K associated with a decreased risk of hip fracture in the Framingham Heart Study (about 250 µg/day) (10), an individual would need to eat a little more than ½ cup of chopped broccoli or a large salad of mixed greens every day. In addition to taking a multivitamin/mineral supplement and eating at least one cup of dark green leafy vegetables daily, replacing dietary saturated fat (e.g., butter and cheese) with monounsaturated fat (e.g., olive and canola oils) will increase dietary vitamin K intake and may also decrease the risk of cardiovascular disease.

Minerals

Calcium

To minimize bone loss, older men (>70 years) and postmenopausal women should consume a total (diet plus supplements) of 1,200 mg/day of calcium. Men aged 51-70 years should consume 1,000 mg of calcium per day. No multivitamin/mineral supplement contains the RDA for calcium (1,000-1,200 mg/day) because the resulting pill would be too large to swallow. If your total daily calcium intake doesn't add up to 1,000 mg, LPI recommends taking an extra calcium supplement with a meal.

Chromium

Although the requirement for chromium is not known to be higher for older adults, one study found that chromium concentrations in hair, sweat, and urine decreased with age (11). Following the Linus Pauling Institute recommendation to take a multivitamin/mineral supplement containing 100% of the daily values (DV) of most nutrients should provide sufficient chromium for most older adults.

Because impaired glucose tolerance and type 2 diabetes are associated with potentially serious health problems, individuals considering high-dose chromium supplementation to treat either condition should do so in collaboration with a qualified health care provider.

Copper

Aging has not been associated with significant changes in the requirement for copper (12); thus, the Linus Pauling Institute recommendation for copper intake in older adults is the same as younger adults. The RDA for copper (900 µg/day for all adults) is sufficient to prevent deficiency, but the lack of clear indicators of copper nutritional status in humans makes it difficult to determine the level of copper intake most likely to promote optimum health or prevent chronic disease. A varied diet should provide enough copper for most people. For those who are concerned that their diet may not provide adequate copper, a multivitamin/mineral supplement will generally provide at least the RDA for copper.

Fluoride

The safety and public health benefits of optimally fluoridated water for prevention of tooth decay in people of all ages have been well established. The Linus Pauling Institute supports the recommendations of the American Dental Association and the Centers for Disease Control and Prevention, which include optimally fluoridated water and the use of fluoride toothpaste, fluoride mouth rinse, fluoride varnish, and when necessary, fluoride supplementation. Due to the risk of fluorosis, any fluoride supplementation should be prescribed and closely monitored by a dentist or physician.

Iodine

The RDA for iodine (150 µg/day for men and women) is sufficient to ensure normal thyroid function. There is presently no evidence that iodine intakes higher than the RDA are beneficial. Most people in the US consume more than sufficient iodine in their diets, making supplementation unnecessary.

Iron

A study in an elderly population found that high iron stores were much more common than iron deficiency (13). Thus, older adults should not generally take nutritional supplements containing iron unless they have been diagnosed with iron deficiency. Moreover, it is extremely important to determine the underlying cause of the iron deficiency, rather than simply treating it with iron supplements.

Magnesium

Older adults are less likely than younger adults to consume enough magnesium to meet their needs and should therefore take care to eat magnesium-rich food in addition to taking a multivitamin/mineral supplement daily. However, no multivitamin/mineral supplement contains 100% of the DV for magnesium. If you don't eat plenty of green leafy vegetables, whole grains, and nuts, you likely are not getting enough magnesium from your diet. Older adults are more likely to have impaired kidney function than younger individuals, they should avoid taking more than 350 mg/day of supplemental magnesium without medical consultation (see the section on Safety in the article on magnesium).

Manganese

The requirement for manganese is not known to be higher for older adults compared to younger adults. However, liver disease is more common in older adults and may increase the risk of manganese toxicity by decreasing the elimination of manganese from the body (see the section on Toxicity in the article on manganese). Manganese supplementation beyond 100% of the Daily Value (DV=2 mg/day) is not recommended.

Molybdenum

Because aging has not been associated with significant changes in the requirement for molybdenum (14), the Linus Pauling Institute recommendation for older adults is the same as that for younger adults. Specifically, the RDA for molybdenum, 45 µg/day for adults of all ages, is sufficient to prevent deficiency. Although the intake of molybdenum most likely to promote optimum health is not known, there is presently no evidence that intakes higher than the RDA are beneficial. Most people in the US consume more than sufficient molybdenum in their diets, making supplementation unnecessary. Following the Linus Pauling Institute's general recommendation to take a multivitamin/mineral supplement that contains 100% of the daily values (DV) for most nutrients is likely to provide 75 µg/day of molybdenum because the DV for molybdenum has not been revised to reflect the most recent RDA. Although the amount of molybdenum presently found in most multivitamin/mineral supplements is higher than the RDA, it is well below the tolerable upper intake level (UL) of 2,000 µg/day and should be safe for older adults.

Phosphorus

At present, there is no evidence that phosphorus requirements of older adults differ from that of younger adults, and a varied diet should easily provide the RDA (700 mg/day) of phosphorus for those over 50 years of age.

Potassium

A diet rich in fruit and vegetables that supplies 2.6-3.7 g/day of potassium is appropriate for healthy older adults because such diets are associated with decreased risk of stroke, hypertension, osteoporosis, and kidney stones. This recommendation does not apply to individuals who have been advised to limit potassium consumption by a health care professional (see the section on Safety in the article on potassium).

Selenium

Aging has not been associated with significant changes in the requirement for selenium. The Linus Pauling Institute supports the recommendation of the Food and Nutrition Board, which is 55 µg/day of selenium for adults of all ages. Although the amount of selenium in multivitamin/mineral supplements varies considerably, multivitamin/mineral supplements rarely provide more than the Daily Value (DV) of 70 µg. The average American diet is estimated to provide about 100 µg/day of selenium (15, 16). Thus, eating a varied diet and taking a daily multivitamin/mineral supplement should provide sufficient selenium for most adults in the US.

Sodium

There is consistent evidence that diets relatively low in salt (5.8 grams/day or less) and high in potassium are associated with decreased risk of high blood pressure and hypertension, as well as the associated risks of cardiovascular and kidney diseases. Diets low in sodium and rich in potassium are likely to be of particular benefit for older individuals, who are at increased risk of high blood pressure. Moreover, the Dietary Approaches to Stop Hypertension (DASH) trial demonstrated that a diet emphasizing fruit, vegetables, whole grains, nuts, and low-fat dairy products substantially lowered blood pressure, an effect that was enhanced by reducing salt intake to 5.8 grams/day or less. For more information on the DASH diet, see the article on Sodium. The Linus Pauling Institute recommends a diet that is rich in fruit and vegetables (at least 5 servings/day) and limits processed foods that are high in salt. Sensitivity to the blood pressure-raising effects of salt increases with age; therefore, consuming diets that are low in salt and high in potassium may especially benefit older adults.

Diets rich in potassium (≥2.6 g/day of potassium) and low in salt (5.8 grams/day or less) are likely to be of particular benefit for older adults, who are at increased risk of high blood pressure along with its associated risks of cardiovascular and kidney diseases. Since sensitivity to the blood pressure-raising effects of salt increases with age, consuming diets that are low in salt and high in potassium may especially benefit older adults.

Zinc

Although the requirement for zinc is not known to be higher for older adults, their average zinc intake tends to be considerably less than the RDA. A reduced capacity to absorb zinc, increased likelihood of disease states that alter zinc utilization, and increased use of drugs that increase zinc excretion may contribute to an increased risk of mild zinc deficiency in older adults. Because the consequences of mild zinc deficiency, such as impaired immune system function, are particularly relevant to the health of older adults, they should pay particular attention to maintaining adequate zinc intake.

Other nutrients

Choline

Little is known regarding the amount of dietary choline most likely to promote optimum health or prevent chronic disease in older adults. At present, there is no evidence to support a different intake of choline from that of younger adults (550 mg/day for men and 425 mg/day for women).

Essential fatty acids

α-Linolenic acid (ALA), an omega-3 fatty acid, and linoleic acid (LA), an omega-6 fatty acid, are considered essential fatty acids because they cannot be synthesized by humans. In 2002, the Food and Nutrition Board of the US Institute of Medicine established adequate intake (AI) levels for omega-6 and omega-3 fatty acids. Essential fatty acid recommendations for adults over the age of 50 are listed in **Table 2**. For more information on ALA and LA, see the article on Essential Fatty Acids.

Table 2. Adequate Intake (AI) for Essential Fatty Acids (17)

Essential Fatty Acid	Men	Women
ALA (>50 years)	1.6 g/day	1.1 g/day
LA (>50 years)	14 g/day	11 g/day

Abbreviations: ALA=α-linolenic acid; LA=linoleic acid; g=grams

International recommendations

Upon request of the European Commission, the European Food Safety Authority (EFSA) proposed adequate intakes (AI) for the essential fatty acids LA and ALA, as well as the long-chain omega-3 fatty acids EPA and DHA (18). EFSA recommends an LA intake of 4% of total energy and an ALA intake of 0.5% of total energy; an AI of 250 mg/day is recommended for EPA plus DHA.

The World Health Organization recommends an acceptable macronutrient distribution range (AMDR) for omega-6 fatty acid intake of 6-11% of energy and for omega-3 fatty acid intake of 0.5-2% of energy (19). Their AMDR for EPA plus DHA is 0.250-2 g/day (the upper limit applying to the secondary prevention of coronary heart disease).

The International Society for the Study of Fatty Acids and Lipids (ISSFAL) recommends for healthy adults an LA intake of 2% energy, ALA intake of 0.7% energy, and a minimum of 500 mg/day of EPA plus DHA for cardiovascular health (20).

American Heart Association recommendation

The American Heart Association recommends that people without documented coronary heart disease (CHD) eat a variety of fish (preferably oily) at least twice weekly (21). Two servings of oily fish provide approximately 500 mg of EPA plus DHA. People with documented CHD are advised to consume approximately 1 g/day of EPA + DHA preferably from oily fish, or to consider EPA + DHA supplements in consultation with a physician. Patients who need to lower serum triglycerides may take 2-4 g/day of EPA + DHA supplements under a physician's care.

Linus Pauling Institute recommendation

The Linus Pauling Institute recommends that generally healthy adults increase their intake of omega-3 fats by eating fish twice weekly and consuming foods rich in α-linolenic acid, such as walnuts, flaxseeds, and flaxseed or canola oil. If you don't regularly consume fish, consider taking a two-gram fish oil supplement several times a week. If you are prone to bleeding or take anticoagulant drugs, consult your physician.

Dietary factors

L-carnitine

Age-related declines in mitochondrial function and increases in mitochondrial oxidant production are thought to be important contributors to the adverse effects of aging. Tissue L-carnitine levels have been found to decline with age in humans and animals (22). One study found that feeding aged rats acetyl-L-carnitine (ALCAR) reversed the age-related declines in tissue L-carnitine levels and also reversed a number of age-related changes in liver mitochondrial function; however, high doses of ALCAR increased liver mitochondrial oxidant production (23). More recently, two studies found that supplementing aged rats with either ALCAR or lipoic acid, a mitochondrial cofactor and antioxidant, improved mitochondrial energy metabolism, decreased oxidative stress, and improved memory (24, 25). Interestingly, co-supplementation of ALCAR and lipoic acid resulted in even greater improvements than either compound administered alone. Likewise, several studies have reported that supplementing rats with both L-carnitine and lipoic acid blunts the age-related increases in reactive oxygen species (ROS), lipid peroxidation, protein carbonylation, and DNA strand breaks in a variety of tissues (heart, skeletal muscle, brain). Improvements in mitochondrial enzyme and respiratory chain activities were also observed (26-33). While these findings are very exciting, it is important to realize that these studies used relatively high doses (100 to 300 mg/kg body weight/day) of the compounds and only for a short time (one month). It is not yet known whether taking relatively high doses of these two naturally occurring substances will benefit rats in the long-term or will have similar effects in humans. Clinical trials in humans are planned, but it will be several years before the results are available. If you choose to take carnitine supplements, the Linus Pauling Institute recommends acetyl-L-carnitine at a daily dose of 500 to 1,000 mg.

Coenzyme Q_{10}

According to the free radical and mitochondrial theories of aging, oxidative damage of cell structures by reactive oxygen species (ROS) plays an important role in the functional declines that accompany aging (34). ROS are generated by mitochondria as a byproduct of ATP production. If not neutralized by antioxidants, ROS may damage mitochondria over time, causing them to function less efficiently and to generate more damaging ROS in a self-perpetuating cycle. Coenzyme Q_{10} plays an important role in mitochondrial ATP synthesis and functions as an antioxidant in mitochondrial membranes. Moreover, tissue levels of coenzyme Q_{10} have been reported to decline with age (35). One of the hallmarks of aging is a decline in energy metabolism in many tissues, especially liver, heart, and skeletal muscle. It has been proposed that age-associated declines in tissue coenzyme Q_{10} levels may play a role in this decline (36). In recent studies, lifelong dietary supplementation with coenzyme Q_{10} did not increase the life spans of rats or mice (37, 38); however, one study showed that coenzyme Q_{10} supplementation attenuates the age-related increase in DNA damage (39). Presently, there is no scientific evidence that coenzyme Q_{10} supplementation prolongs life or prevents age-related functional declines in humans.

Lipoic acid

Lipoic acid alone or in combination with other antioxidants or L-carnitine has been found to improve measures of memory in animal models of age-associated cognitive decline, including rats (24, 25), mice (40), and dogs (41). However, it is not clear whether oral lipoic acid supplementation can slow cognitive decline related to aging or other pathology in humans. An uncontrolled, open-label trial in nine patients with Alzheimer's disease and related dementias, who were also taking acetylcholinesterase inhibitors, reported that oral supplementation with 600 mg/day of racemic lipoic acid appeared to stabilize cognitive function over a one-year period (42). However, the significance of these findings is difficult to assess without a control group for comparison. A randomized controlled trial found that oral supplementation with 1,200 mg/day of racemic lipoic acid for 10 weeks was of no benefit in treating HIV-associated cognitive impairment (43). Although studies in animals suggest that lipoic acid may be helpful in slowing age-related cognitive decline, randomized controlled trials are needed to determine whether lipoic acid supplementation is effective in preventing or slowing cognitive decline associated with age or neurodegenerative disease. If you choose to take lipoic acid supplements, the Linus Pauling Institute recommends a daily dose of 200-400 mg/day of racemic lipoic acid for generally healthy people.

Flavonoids

The prevalence of several neurodegenerative diseases increases with advanced age. Inflammation, oxidative stress, and transition metal accumulation appear to play a role in the pathology of several neurodegenerative diseases, including Parkinson's disease and Alzheimer's disease. Because flavonoids have anti-inflammatory, antioxidant and metal-chelating properties, scientists are interested in the neuroprotective potential of flavonoid-rich diets or individual flavonoids. At present, the extent to which various dietary flavonoids and flavonoid metabolites cross the blood-brain barrier in humans is not known (44). Although flavonoid-rich diets and flavonoid administration have been found to prevent cognitive impairment associated with aging and inflammation in some animal studies (45-48), prospective cohort studies have not found consistent inverse associations between flavonoid intake and the risk of dementia or neurodegenerative disease in humans (49-53).

In a cohort of Japanese-American men followed for 25-30 years, flavonoid intake from tea during midlife was not associated with the risk of Alzheimer's or other types of dementia in late life (49). Surprisingly, higher intakes of isoflavone-rich tofu during midlife were associated with cognitive impairment and brain atrophy in late life (see the article on Soy Isoflavones) (50). A prospective study of Dutch adults found that total dietary flavonoid intake was not associated with the risk of developing Parkinson's disease (51) or Alzheimer's disease (52), except in current smokers whose risk of Alzheimer's disease decreased by 50% for every 12 mg increase in daily flavonoid intake. In contrast, a study of elderly French men and women found that those with the lowest flavonoid intakes had a risk of developing dementia over the next five years that was 50% higher than those with the highest intakes (53). More recently, a study in 1,640 elderly men and women found that those with higher dietary flavonoid intake (>13.6 mg/day) had better cognitive performance at baseline and experienced significantly less age-related cognitive decline over a 10-year period than those with a lower flavonoid intake (0-10.4 mg/day) (54). Additionally, a randomized, double-blind, placebo-controlled clinical trial in 202 postmenopausal women reported that daily supplementation with 25.6 g of soy protein (containing 99 mg of isoflavones) for one year did not improve cognitive function (55). However, a randomized, double-blind, placebo-controlled, cross-over trial in 77 postmenopausal women found that six-month supplementation with 60 mg/day of isoflavones improved some measures of cognitive performance (56). Although scientists are interested in the potential of flavonoids to protect the aging brain, it is not yet clear how flavonoid consumption affects neurodegenerative disease risk in humans.

Resveratrol

Caloric restriction is known to extend the lifespan of a number of species, including yeast, worms, flies, fish, rats, and mice (57). In yeast (Saccharomyces cerevisiae), caloric restriction stimulates the activity of an enzyme known as Silent information regulator 2 protein (Sir2) or sirtuin (58). Yeast Sir2 is a nicotinamide adenine dinucleotide (NAD)-dependent deacetylase enzyme that removes the acetyl group from acetylated lysine residues in target proteins.

Providing resveratrol to yeast increased Sir2 activity in the absence of caloric restriction and extended the replicative (but not the chronological) lifespan of yeast by 70% (59). Resveratrol feeding also extended the lifespan of worms (*Caenorhabditis elegans*) and fruit flies (*Drosophila melanogaster*) by a similar mechanism (60). Additionally, resveratrol dose-dependently increased the lifespan of a vertebrate fish (*Nothobranchius furzeri*) (61). Resveratrol was also found to extend the lifespan of mice on a high-calorie diet such that their lifespan was similar to that of mice fed a standard diet 62. Although resveratrol increased the activity of the Sir2 homologous human sirtuin 1 (SIRT1) in the test tube (59), there are no epidemiological data to link resveratrol, SIRT1 activation, and extended human lifespan. Moreover, the supraphysiological concentrations of resveratrol required to increase human SIRT1 activity were considerably higher than concentrations that have been measured in human plasma after oral consumption.

The Linus Pauling Institute provides dietary and lifestyle recommendations for generally healthy individuals interested in optimum health and prevention of chronic diseases such as cardiovascular disease (heart disease and stroke), diabetes, cancer, and osteoporosis. These recommendations are contained in the Linus Pauling Institute's Rx for Health.

Glossary: A

Acetylation
the addition of an acetyl group (-$COCH_3$) group to a molecule.

Achlorhydria
the absence of hydrochloric acid in gastric juice.

Acidic
having a pH of less than 7.

Acne vulgaris
a condition of the skin characterized by the presence of comedones.

Acrodermatitis enteropathica
a rare, inherited disorder of impaired zinc absorption.

Actinic lentigines
hyperpigmented patches that occur in sun-exposed skin; also known as liver spots or age spots.

Acute
having a short and relatively severe course.

Acute-phase reactant protein
also called acute-phase protein; plasma protein that is synthesized by the liver during acute inflammation. Examples include C-reactive protein (CRP), fibrinogen, serum amyloid A protein, and von Willebrand factor.

Action potential
the electrochemical signal transmitted in the cell membrane of a neuron or muscle cell. Also called nerve impulse.

Adipose tissue
specialized connective tissue that functions to store body fat as triglycerides.

Adjunct therapy
a treatment or therapy used in addition to another, not alone.

Adrenal glands
a pair of small glands, located above the kidneys, consisting of an outer cortex and inner medulla. The adrenal cortex secretes cortisone-related hormones and the adrenal medulla secretes epinephrine (adrenaline) and norepinephrine (noradrenaline).

Aglycone
the nonsugar component of a glycoside. Cleavage of the glycosidic bond of a glycoside results in the formation of a sugar and an aglycone.

AI
adequate intake. Established by the Food and Nutrition Board of the US Institute of Medicine, the AI is a recommended intake value based on observed or experimentally determined estimates of nutrient intake by a group of healthy people that are assumed to be adequate. An AI is established when an RDA cannot be determined.

AIDS
acquired immune deficiency syndrome. AIDS is caused by the HIV (Human Immunodeficiency Virus) virus, which attacks the immune system, leaving the infected individual vulnerable to opportunistic infections.

Alkaline
basic; having a pH of more than 7.

Alkaloid
a plant-derived compound that is biologically active, contains a nitrogen in a heterocyclic ring, is alkaline, has a complex structure, and is of limited distribution in the plant kingdom.

Allele
one of a set of alternative forms of a gene. Diploid cells possess two homologous chromosomes (one derived from each parent) and therefore two copies of each gene. In a diploid cell, a gene will have two alleles, each occupying the same position on homologous chromosomes.

Alopecia
loss of hair.

Alzheimer's disease
the most common cause of dementia in older adults. Alzheimer's disease is characterized by the formation of amyloid plaque in the brain and nerve cell degeneration. Symptoms include memory loss and confusion, which worsen over time.

Amino acid
an organic molecule that contains an amino group (-NH_2) and a carboxyl group (-COOH); amino acids are as the building blocks of proteins.

AMP
adenosine monophosphate. A important compound in energy metabolism. Addition of two phosphates to AMP forms ATP.

Amphipathic
a chemical compound having both hydrophilic (water-loving, polar) and lipophilic (fat-loving, nonpolar) properties.

Amyloid plaque
aggregates of a peptide called amyloid-β, which accumulate and form deposits in the brain in Alzheimer's disease.

Amyotrophic lateral sclerosis (ALS)
a rapidly progressive and fatal neurological disease caused by degeneration of motor neurons that control voluntary muscle movement. Also known as Lou Gehrig's disease.

Anabolism
the synthesis of large complex molecules from simple molecules.

Anaerobic
refers to the absence of oxygen or the absence of a need for oxygen.

Analog
a chemical compound that is structurally similar to another but differs slightly in composition (e.g., the replacement of one functional group by another).

Anaphylaxis
a rapidly developing and severe systemic allergic reaction. Symptoms may include swelling of the tongue, throat, and trachea, which can result in difficulty breathing, shock and loss of consciousness. If not treated rapidly, anaphylaxis can be fatal.

Anemia
the condition of having less than the normal number of red blood cells or hemoglobin in the blood, resulting in diminished oxygen transport. Anemia has many cause, including iron, vitamin B_{12}, or folate deficiency; bleeding; abnormal hemoglobin formation (e.g., sickle cell anemia); rupture of red blood cells (hemolytic anemia); and bone marrow diseases.

Anencephaly
a birth defect, known as a neural tube defect, resulting from failure of the upper end of the neural tube to close during embryonic development. Anencephaly is a devastating and sometimes fatal birth defect resulting in the absence of most or all of the cerebral hemispheres.

Angina pectoris
pain generally experienced in the chest, but sometimes radiating to the arms or jaw, due to a lack of oxygen supply to the heart muscle.

Angiogenesis
the development of new blood vessels.

Angiography (coronary)
imaging of the coronary arteries used to identify the location and severity of any obstructions. Coronary angiography typically involves the administration of a contrast medium and imaging of the coronary arteries using an X-ray based technique.

Anion
a negatively charged ion.

Anotia
the absence of the external ear.

Antagonist
a substance that counteracts or nullifies the biological effects of another, such as a compound that binds to a receptor but does not elicit a biological response.

Antenatal
before birth; also called prenatal.

Anthropometric
relating to the measurement of the human body.

Antibody
a specialized protein produced by white blood cells (lymphocytes) that recognizes and binds to foreign proteins or pathogens in order to neutralize them or mark them for destruction.

Anticoagulant
a class of compounds that inhibit blood clotting.

Anticonvulsant
a class of medication used to prevent seizures.

Antigen
a substance that is capable of eliciting an immune response.

Antihistamine
a chemical that blocks the effect of histamine in a susceptible tissues. Histamine is released by immune cells during an allergic reaction and also during infection with viruses that cause the common cold. The interaction of histamine with the mucus membranes of the eyes and nose results in "watery eyes" and the "runny nose" often accompanying allergies and colds. Antihistamines can help alleviate such symptoms.

Antimicrobial
capable of killing or inhibiting the growth of microorganisms, such as bacteria.

Antioxidant
any substance that prevents or reduces damage caused by reactive oxygen species (ROS) or reactive nitrogen species (RNS).

Antiresorptive agent
a medication or hormone that inhibits bone resorption.

Anxiolytic
an agent that decreases anxiety.

Apgar score
a scoring system used to assess the physical condition of a newborn immediately after birth. Criteria evaluated include respiratory effort, heart rate, skin coloration, muscle tone, and response to stimulation.

Apoptosis
gene-directed cell death or programmed cell death that occurs when age, condition, or state of cell health dictates. Cells that die by apoptosis do not usually elicit the inflammatory responses that are associated with necrosis. Cancer cells are resistant to apoptosis.

Aqueous
referring to water or a solution containing water.

Arrhythmia
an abnormal heart rhythm. The heart rhythm may be too fast (tachycardia), too slow (bradycardia) or irregular. Some arrhythmias, such as ventricular fibrillation, may lead to cardiac arrest if not treated promptly.

Asphyxia
a lack of oxygen or excess carbon dioxide in the body that causes unconsciousness.

Asthma
a chronic inflammatory disease of the airways, characterized by recurrent episodes of reversible airflow obstruction.

Astrocyte
a type of glial cell in the central nervous system.

Ataxia
a lack of coordination or unsteadiness usually related to a disturbance in the cerebellum, a part of the brain that regulates coordination and equilibrium.

Atherogenic
capable of producing atherosclerosis.

Atherosclerosis
an inflammatory disease resulting in the accumulation of cholesterol-laden plaque in artery walls. Rupture of atherosclerotic plaque results in clot formation, which may result in myocardial infarction or ischemic stroke.

ATP
adenosine triphosphate. An important compound for the storage of energy in cells, as well as the synthesis of nucleic acids.

Atria
(singular: atrium) two upper chambers of the heart that receive blood from the veins and contract to force that blood into the ventricles.

Atrial fibrillation
a cardiac arrhythmia, characterized by rapid, uncoordinated beating of the atria, which results in ineffective atrial contractions. Atrial fibrillation is known as a supraventricular arrhythmia because it originates above the ventricles.

Atrophic gastritis
a chronic inflammation of the lining of the stomach, which ultimately results in the loss of glands in the stomach (atrophy) and decreased stomach acid production.

Atrophy
a decrease in size or wasting away of a body part or tissue.

Attrition
a reduction in number.

Autoimmune disease
a condition in which the body's immune system reacts against its own tissues.

Autophosphorylation
the phosphorylation by a protein of one or more of its own amino acid residues. Autophosphorylation does not necessarily occur on the same polypeptide chain as the catalytic site. In a dimer, one subunit may phosphorylate the other.

Autosomal

refers to a trait or gene that is not located on the X or Y chromosome (not sex-linked).

Axon
long extension of a neuron that transmits nerve impulses away from the cell body toward other neurons or muscle cells.

Glossary B:

Back to top

Bacteria
single-celled organisms that can exist independently, symbiotically (in cooperation with another organism) or parasitically (dependent upon another organism, sometimes to the detriment of the other organism). Examples of bacteria include acidophilus (found in yogurt); streptococcus the cause of strep throat; and E. coli (a normal intestinal bacteria, as well as a disease-causing agent).

Balance study
a nutritional balance study involves the measurement of the intake of a specific nutrient as well as the elimination of that nutrient in urine, feces, sweat, etc. If intake is greater than loss of a particular nutrient the individual is said to be in "positive balance." If intake is less than loss, an individual is said to be in "negative balance" for the nutrient of interest.

Bariatrics
the branch of medicine that relates to the treatment of obesity.

Benign
not malignant.

Benign prostatic hyperplasia
the term used to describe a noncancerous enlargement of the prostate.

Bias
any systematic error in an epidemiological study that results in an incorrect estimate of the association between an exposure and disease risk.

Bile
a yellow, green fluid made in the liver and stored in the gallbladder. Bile may then pass through the common bile duct into the small intestine where some of its components aid in the digestion of fat.

Bile acids
components of bile, which are formed by the metabolism of cholesterol, and aid in the digestion of fats.

Bioavailability
the fraction of an administered compound that reaches the systemic circulation and is transported to site of action (target tissue).

Biomarker
a physical, functional, or biochemical indicator of a physiological or disease process.

Biotransformation enzymes (phase I and phase II)
enzymes involved in the metabolism and elimination of a variety of exogenous (drugs, toxins and carcinogens) and endogenous compounds (steroid hormones). In general, phase I biotransformation enzymes, including those of the cytochrome P450 family, catalyze reactions that increase the reactivity of fat-soluble compounds and prepare them for reactions catalyzed by phase II biotransformation enzymes. Reactions catalyzed by phase II enzymes generally increase water solubility and promote the elimination of these compounds.

Bipolar disorder
a mood disorder previously called “manic-depressive illness.” Bipolar disorder is characterized by severe alterations in mood. During “manic” episodes, a person may experience extreme elevation in energy level and mood (euphoria) or extreme agitation and irritability. Episodes of depressed mood are also common in bipolar disorder.

Body mass index (BMI)
body weight in kilograms divided by height in meters squared. In adults, BMI is a measure of body fat: underweight, <18.5; normal weight, 18.5-24.9; overweight, 25-29.9; obese, ≥30. Calculate your BMI.

Bone mineral density (BMD)
the amount of mineral in a given area of bone. BMD is positively associated with bone strength and resistance to fracture, and measurements of BMD are used to diagnose osteoporosis.

Bone remodeling
the continuous turnover process of bone that includes bone resorption and bone formation. An imbalance in the regulation of the two contrasting events of bone remodeling (bone resorption and bone formation) increases the fragility of bone and may lead to osteoporosis.

Borborygmus
a rumbling sound caused by gas movement in the intestines; sometimes called "stomach rumble."

Branched-chain amino acids
the essential amino acids: leucine, isoleucine, and valine.

Bronchitis, chronic
long-standing inflammation of the airways, characterized by excess production of sputum, leading to a chronic cough and obstruction of air flow. Cigarette smoking is the most common cause of chronic bronchitis.

Buffer
a chemical used to maintain the pH of a system by absorbing hydrogen ions (which would make it more acidic) or absorbing hydroxyl ions (which would make it more alkaline).

Glossary: C

Back to top

C-reactive protein (CRP)
a protein that is produced in the liver in response to inflammation. CRP is a biomarker of inflammation that is strongly associated with the risk of cardiovascular events, such as myocardial infarction and stroke.

Calcification
the process of deposition of calcium salts. In the formation of bone this is a normal condition. In other organs, this could be an abnormal condition; for example, calcification of the aortic valve causes narrowing of the passage (aortic stenosis).

Cancer
refers to abnormal cells, which have a tendency to grow uncontrollably and metastasize or spread to other areas of the body. Cancer can involve any tissue of the body and can have different forms in one tissue. Cancer is a group of more than 100 different diseases.

Carbohydrate
considered a macronutrient because carbohydrates provide a significant source of calories (energy) in the diet. Chemically, carbohydrates are neutral compounds composed of carbon, hydrogen and oxygen. Carbohydrates come in simple forms known as sugars and complex forms, such as starches and fiber.

Carboxylase
an enzyme that catalyzes carboxylation reactions.

Carboxylation
the introduction of a carboxyl group (-COOH) or carbon dioxide into a compound.

Carcinogen
a cancer-causing agent; adjective: carcinogenic.

Carcinogenesis
the formation of cancer cells from normal cells.

Carcinoid syndrome
the pattern of symptoms exhibited by individuals with carcinoid tumors. Carcinoid tumors secrete excessive amounts of the neurotransmitter, serotonin. Symptoms may include flushing, diarrhea, and sometimes wheezing.

Cardiac output
volume of blood pumped by the heart in a specified time period.

Cardiomyopathy
literally, disease of the heart muscle that often leads to abnormal function.

Cardiovascular
referring to the heart and blood vessels.

Cardiovascular disease
literally, diseases affecting the heart and blood vessels. The term has come to encompass a number of conditions that result from atherosclerosis, including myocardial infarction (heart attack), congestive heart failure, and stroke.

Carnitine
a compound that is required to transport long-chain fatty acids across the inner membrane of the mitochondria, in the form of acyl-carnitine, where they can be metabolized for energy.

Carotid arteries
the left and right common carotid arteries are the principal blood vessels that supply oxygenated blood to the head and neck. Each has two main branches, the external and internal carotid artery.

Cartilage
a soft, elastic tissue that composes most of the skeleton of vertebrate embryos and except for a small number of structures is replaced by bone during ossification in the higher vertebrates. Cartilage cushions joints, connects muscles with bones, and makes up other parts of the body, such as the larynx (voice box) and the outside portion of the ears.

Case-control study
a study in which exposures of people who have been diagnosed with a disease (cases) are compared to those of people without the disease (controls). The results of case-control studies are more likely to be distorted by bias in the selection of cases and controls (selection bias) and dietary recall (recall bias) than prospective cohort studies.

Case report
a report that decribes an individual case of a disease or medical condition. This type of research cannot indicate causality but may indicate areas for further research.

Catabolism
the breakdown of complex molecules into smaller ones, accompanied by the release of energy.

Catalyze
to increase the speed of a chemical reaction without being changed in the overall reaction process. See enzyme.

Cataract
clouding of the lens of the eye. As cataracts progress, they can impair vision.

Catecholamine
a substance with a specific chemical structure (a benzene ring with two adjacent hydroxyl groups and a side chain of ethylamine) that functions as a hormone or neurotransmitter. Examples include epinephrine, norepinephrine, and dopamine.

Cation
a positively charged ion.

Celiac disease
also known as celiac sprue, celiac disease is an inherited disease in which the intestinal lining is inflamed in response to the ingestion of a protein known as gluten. Treatment of celiac disease involves the avoidance of gluten, which is present in many grains, including wheat, rye, oats, and barley. Inflammation and atrophy of the lining of the small intestine leads to impaired nutrient absorption.

Cell adhesion molecule
a molecule on the outside surface of cells that binds to other cells or to the extracellular matrix (material surrounding cells). Cell adhesion molecules influence many important functions, including the entry of immune cells into the arterial wall.

Cell cycle
the orderly sequence of stages that a cell passes through between one cell division (mitosis) and the next. The cell cycle can be divided into four stages: the M (mitosis) phase, in which nuclear and cytoplasmic division occurs; the G1 phase or interphase; the S (synthesis) phase, in which DNA replication occurs; and the G2 phase, a quiescent period prior to the next M phase.

Cell membrane
also called a plasma membrane; the barrier that separates the contents of a cell from its outside environment and controls what moves in and out of the cell. A mammalian cell membrane consists of a phospholipid bilayer with embedded proteins and cholesterol.

Cell signaling
communication among individual cells so as to coordinate their behavior to benefit the organism as a whole. Cell-signaling systems elucidated in animal cells include cell-surface and intracellular receptor proteins, GTP-binding proteins, as well as protein kinases and protein phosphatases (enzymes that phosphorylate and dephosphorylate proteins).

Central nervous system (CNS)
the brain, spinal cord, and spinal nerves.

Ceramide
a specialized type of lipid comprised of a sphingosine backbone with fatty acid side chains. Ceramides function as signaling molecules and are critical structural components in cell membranes.

Cerebral
relating to the brain.

Cerebrospinal fluid
the fluid that bathes the brain and spinal cord.

Cerebrovascular disease
disease involving the blood vessels supplying the brain, including cerebrovascular accident (CVA), also known as a stroke.

Cerebrum
the upper part of the brain that is involved in conscious mental functions.

Ceruloplasmin
a ferroxidase enzyme that has the capacity to oxidize ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}), which can be loaded onto the iron-transport protein, transferrin.

Cervical intraepithelial neoplasia (CIN)
a term used to describe abnormal growth of cells on the surface of the uterine cervix. CIN1 is also known as low-grade squamous intraepithelial lesion (LSIL). CIN2 and CIN3 are also known as high-grade squamous intraepithelial lesions (HSIL). Although these abnormal cells are not cancerous, they may progress to cervical cancer.

Chelate
the combination of a metal with an organic molecule to form a ring-like structure known as a chelate. Chelation of a metal may inhibit or enhance its bioavailability.

Chemotaxis
movement of a cell or organism toward or away from a chemical stimulus.

Chemotherapy
literally, treatment with drugs. Commonly used to describe the systemic use of drugs to kill cancer cells, as a form of cancer treatment.

Cholecystectomy
removal of the gallbladder.

Cholestatic liver disease
liver disease resulting in the cessation of bile excretion. Cholestasis may occur in the liver, gallbladder, or bile duct (duct connecting the gall bladder to the small intestine).

Cholesterol
a compound that is an integral structural component of cell membranes and a precursor in the synthesis of steroid hormones. Dietary cholesterol is obtained from animal sources, but cholesterol is also synthesized by the liver. Cholesterol is carried in the blood by lipoproteins. In atherosclerosis, cholesterol accumulates in plaques on the walls of some arteries.

Cholinergic
resembling acetylcholine in action, a cholinergic drug for example. Cholinergic nerve fibers liberate or are activated by the neurotransmitter, acetylcholine.

Chorionic villus sampling (CVS)
a procedure for obtaining a small sample of tissue from the placenta (chorionic villi) for the purpose of prenatal diagnosis of genetic disorders. CVS can be performed between 9 to 12 weeks of pregnancy.

Chromatin
complex of DNA, RNA, and proteins that comprise chromosomes.

Chromosome
a structure in the nucleus of a cell that contains genes. Chromosomes are composed of DNA and associated proteins. Normal human cells contain 46 chromosomes (22 pairs of autosomes and 2 sex chromosomes).

Chronic disease
an illness lasting a long time. By definition of the US Center for Health Statistics, a chronic disease is a disease lasting three months or more.

Chronic obstructive pulmonary disease (COPD)
a term that includes emphysema and chronic bronchitis, two chronic lung diseases that are characterized by airway obstruction.

Chylomicrons
triglyceride-rich lipoproteins that deliver dietary triglycerides from the intestine to the tissues immediately after a meal. Chylomicrons release their triglycerides to tissue through the activity of lipoprotein lipase enzymes in tissue capillary beds. When they are depleted of most of their triglycerides, chylomicron remnants are taken up by the liver, where the lipids and cholesterol that remain are excreted in bile or incorporated into other lipoproteins.

Chyme
the mass of partially digested food that exits the stomach and enters the duodenum of the small intestine.

Cirrhosis
a condition characterized by irreversible scarring of the liver, leading to abnormal liver function. Cirrhosis has a number of different causes, including chronic alcohol use and viral hepatitis B and C.

Citric acid cycle
the metabolic pathway in the mitochondria that oxidizes acetyl compounds form food to carbon dioxide and water. Also referred to as the Krebs cycle and the tricarboxylic acid (TCA) cycle.

Clinical trial
an intervention trial generally used to evaluate the efficacy and/or safety of a treatment or intervention in human participants.

Clone
an exact copy of a DNA segment; produced by recombinant DNA technology.

Coagulation
the process involved in blood clot formation.

Coenzyme
a molecule that binds to an enzyme and is essential for its activity but is not permanently altered by the reaction. Many coenzymes are derived from vitamins.

Cofactor
a compound that is essential for the activity of an enzyme.

Cognition
mental process of thought; includes brain functions like attention, memory, planning, developing strategies, and problem solving.

Cognitive
referring to the processes of cognition.

Cohort
a group of people who are followed over time as part of an epidemiological study.

Cohort study
a study that follows a large group of people over a long period of time, often 10 years or more. In cohort studies, dietary information is gathered before disease occurs, rather than relying on recall after disease develops.

Collagen
a fibrous protein that is the basis for the structure of skin, tendon, bone, cartilage and all other connective tissue.

Collagenous matrix (of bone)
the organic (nonmineral) structural element of bone. Collagen is a fibrous protein that provides the organic matrix upon which bone mineralize crystallizes.

Colon
the portion of the large intestine that extends from the end of the small intestine to the rectum. The colon removes water from digested food after it has passed through the small intestine and stores the remaining stool until it can be evacuated.

Colorectal adenoma
a polyp or growth in the lining of the colon or rectum. Although they are not cancerous, colorectal adenomas may develop into colorectal cancer over time.

Colorectal cancer
cancer of the colon (large intestine) or rectum.

Colostomy
the surgical construction of an artificial anus by connecting the colon to an opening in the abdominal wall.

Comedone
a pilosebaceous unit blocked with sebum and inflammatory cells.

Complement
system of serum proteins that function to help destroy invading microorganisms.

Concomitant
accompanying. "Concomitant intake" refers to the intake of two compounds at the same time.

Conditionally essential nutrient
although not strictly considered a nutrient due to endogenous synthesis, certain conditions (e.g., stress, aging) may result in the demand exceeding the body's capacity for synthesis, rendering a conditionally essential nutrient.

Confidence interval (CI)
a statistical measure of certainty. A CI defines the range within which we can be certain that a result is not due to chance alone.

Confounder
an extraneous factor in an observational study that distorts or biases an association between an exposure and the measured outcome. Confounders are associated with the exposure and outcome of interest, but they are not in the causal pathway.

Congenital anomaly
a birth defect, a condition present at birth.

Congenital hypothyroidism
deficiency of thyroid gland activity in newborn infants.

Congenital malformation
birth defects.

Congestive heart failure (CHF)
a condition, in which the heart loses the ability to pump blood efficiently enough to meet the demands of the body. Symptoms may include edema (swelling), shortness of breath, weakness and exercise intolerance.

Conjugate
a compound formed through joining (conjugation) of at least two chemical compounds.

Conjugation
the formation of a water-soluble derivative of a chemical by its combination with another compound, such as glutathione, glucuronate, or sulfate.

Cornea
the transparent covering of the front of the eye that transmits and focuses light into the eye.

Corneocyte
a metabolically inactive, flattened cell of the stratum corneum. Corneocytes are formed from keratinocytes in a process termed cornification. Corneocytes are metabolically inactive and will eventually be cast off from the body when new corneocytes are generated underneath them.

Cornification
the process by which a keratinocyte becomes a corneocyte in the outer, visible layer of the epidermis. This is marked by a loss of intracellular organelles, the production of specialized proteins and lipids, and the generation of a thick protein envelope just inside the cell membrane. Corneocytes are metabolically inactive and will eventually be cast off from the body when new corneocytes are generated underneath them.

Coronary angioplasty
a procedure used to open an occluded coronary artery. A flexible hollow catheter is inserted into a large blood vessel in the groin and advanced to the heart. At the site of the occlusion, the balloon tip of the catheter is inflated and the occluded coronary artery is dilated. Coronary angioplasty is also known as percutaneous transluminal coronary angioplasty or PTCA.

Coronary artery
one of the vessels that supply oxygenated blood to the heart muscle itself. They are called coronary arteries because they encircle the heart in the form of a crown.

Coronary artery bypass graft (CABG)
a surgical procedure used to create new routes around obstructions in coronary arteries and restore adequate blood flow to the heart muscle.

Coronary heart disease (CHD)
sometimes called coronary artery disease or coronary disease, coronary heart disease is the result of atherosclerosis of the coronary arteries. Atherosclerosis may result in narrowing or blockage of the coronary arteries and is the underlying cause of myocardial infarction (heart attack).

Cortical bone
also known as compact bone, the type of bone that forms the outer surface of all bones. The small bones of the wrists, hands, and feet are entirely cortical bone.

Corticosteroid
any of the steroid hormones made by the cortex (outer layer) of the adrenal gland. Cortisol is a corticosteroid. A number of medications are analogs of natural corticosteroid hormones.

Covalent bond
a chemical bond in which electrons are shared between atoms.

Craniosynostosis
abnormal skull shape due to the fibrous sutures of the skull having turned into bone prematurely.

Creatine phosphate
a high-energy compound found in muscle cells, which is used to convert ADP into ATP by donating phosphate molecules to the ADP. ATP is the molecule that is converted into ADP with a release of energy that the body then uses.

Cretinism
a condition that can result from a severe form of congenital hypothyroidism. Cretinism occurs in two forms, although there is considerable overlap. The neurologic form is characterized by mental and physical retardation and deafness. It is the result of maternal iodine deficiency that affects the fetus before its own thyroid is functional. The myxedematous or hypothyroid form is characterized by short stature and mental retardation. In addition to iodine deficiency, the hypothyroid form has been associated with selenium deficiency and the presence of goitrogens in the diet that interfere with thyroid hormone production.

Crohn's disease
an inflammatory bowel disease that usually affects the lower part of the small intestine or upper part of the colon but may affect any part of the gastrointestinal tract.

Cross-over trial
a clinical trial where at least two interventions or treatments are applied to the same individuals after an appropriate wash-out period. One of the treatments is often a placebo. In a randomized cross-over design, interventions are applied in a randomized order to ensure that the order of treatments did not contribute to the outcome.

Cross-sectional study
a study of a group of people at one point in time to determine whether an exposure is associated with the occurrence of a disease. Because the disease outcome and the exposure (e.g., nutrient intake) are measured at the same time, a cross-sectional study provides a “snapshot” view of their relationship. Cross-sectional studies cannot provide information about causality.

Cutaneous
related to or affecting the skin.

Cystic fibrosis (CF)
a hereditary disease caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTCR) gene. Cystic fibrosis is characterized by the production of abnormal secretions, leading to the accumulation of mucus in the lungs, pancreas, and intestine. This build-up of mucus causes difficulty breathing and recurrent lung infections, as well as problems with nutrient absorption due to problems in the pancreas and intestines.

Cytochrome P450
a family of phase I biotransformation enzymes that play an important role in the metabolism and elimination of drugs, toxins, carcinogens, and endogenous compounds, such as steroid hormones.

Cytokine
a protein made by cells that affects the behavior of other cells. Cytokines act on specific cytokine receptors in the cells they affect.

Cytoplasm
the contents of a cell, excluding the nucleus.

Cytosol
the water-soluble contents of a cell's cytoplasm, excluding the organelles.

Glossary: D

Back to top

De novo synthesis
the formation of an essential molecule from simple precursor molecules.

Debridement
the removal of necrotic or infected tissue or foreign material from a wound.

Decarboxylation
a chemical reaction involving the removal of a carboxyl (-COOH) group from a compound.

Dementia
significant impairment of intellectual abilities, such as attention, orientation, memory, judgment or language. By definition, dementia is not due to major depression or psychosis. Alzheimer’s disease is the most common cause of dementia in older adults.

Dendrite
a branched extension of a neuron that receives signals from other neurons.

Dendritic cell
an immune cell that functions in antigen presentation and activation of T lymphocytes. Dendritic cells have a branched morphology that resembles dendrites of a neuron.

Dental caries
cavities or holes in the outer two layers of a tooth—the enamel and the dentin. Dental caries are caused by bacteria, which metabolize carbohydrates (sugars) to form organic acids that dissolve tooth enamel.

Depletion-repletion study
a nutritional study designed to determine the requirement for a specific nutrient. Generally, subjects are placed on a diet designed to deplete them of a specific nutrient over time. Once depletion is achieved, gradually increasing amounts of the nutrient under study are added to the diet until the individual shows evidence of sufficiency or repletion.

Dermatitis
inflammation of the skin. This term is often used to describe a skin rash.

Dermatoses
any skin disease, especially one not characterized by inflammation.

Dermis
the layers of skin below the epidermis that support the epidermis in both structure and function. Although the majority of cells in this layer are fibroblasts supported by a collagen network, blood vessels, immune cells, and adipose tissue are also found in the dermis.

DEXA or DXA
dual-energy X-ray absorptiometry. A precise instrument that uses the energy from very small doses of X-rays to determine bone mineral density (BMD) and to diagnose and follow the treatment of osteoporosis.

Diabetes mellitus
a chronic metabolic disease, characterized by abnormally high blood glucose (sugar) levels, resulting from the inability of the body to produce or respond to insulin. Type 1 diabetes mellitus, formerly known as insulin-dependent or juvenile-onset diabetes, is usually the result of autoimmune destruction of the insulin secreting β-cells of the pancreas. The most common form of diabetes is type 2 diabetes mellitus, formerly known as noninsulin-dependent or adult onset diabetes, which develops when the tissues of the body become less sensitive to insulin secreted by the pancreas.

Diabetic ketoacidosis
a potentially life-threatening condition characterized by ketosis (elevated levels of ketone bodies in the blood) and acidosis (increased acidity of the blood). Ketoacidosis occurs when diabetes is not adequately controlled.

Dialysis
a medical procedure to filter waste products from the blood. Dialysis is needed to perform the work of the kidneys if they can no longer function effectively. Two types of dialysis are hemodialysis and peritoneal dialysis.

Diastolic blood pressure
the lowest arterial blood pressure during the heart beat cycle, and the second number in a blood pressure reading (e.g., 120/80).

Differentiation
changes in a cell resulting in its specialization for specific functions, such as those of a nerve cell. In general, differentiation of cells leads to a decrease in proliferation.

Diffusion
a passive process, in which particles in solution move from a region of higher concentration to one of lower concentration.

Dimer
a complex of two molecules, usually proteins. Heterodimers are complexes of two different molecules, while homodimers are complexes of two of the same molecule.

Diuretic
an agent that increases the formation of urine by the kidneys, resulting in water loss from the individual using the diuretic.

Diverticulitis
inflammation or infection of diverticula in the colon (see diverticulosis), characterized by abdominal pain, fever, and constipation.

Diverticulosis
a condition characterized by the formation of small pouches (diverticula) in the colon. Although most people with diverticulosis experience no symptoms, about 15-20% may develop pain or inflammation, known as diverticulitis.

DNA
deoxyribonucleic acid; a double-stranded nucleic acid composed of many nucleotides. The nucleotides in DNA are each composed of a nitrogen-containing base (adenine, guanine, cytosine, or thymine), a five-carbon sugar (deoxyribose), and a phosphate group. The sequence of bases in DNA encodes the genetic information required to synthesize proteins.

DNA adduct
the complex formed when a chemical forms a covalent bond with DNA.

Dominant trait
a trait that is expressed when only one copy of the gene responsible for the trait is present.

Double-blind
refers to a study in which neither the investigators administering the treatment nor the participants know which participants are receiving the experimental treatment and which are receiving the placebo.

DRI
dietary reference intake. Refers to a set of at least four nutrient-based reference values (RDA, AI, UL, EAR), each with a specific use in defining recommended dietary intake levels for individual nutrients in the US. The DRIs are determined by expert panels appointed by the Food and Nutrition Board of the Institute of Medicine.

DV
daily value. Refers to the dietary reference values required as the basis for declaring nutrient content on all products regulated by the US Food and Drug Administration (FDA), including nutritional supplements. The DVs for vitamins and minerals reflect the National Academy of Sciences' 1968 RDAs, and do not reflect the most up-to-date Dietary Reference Intakes.

Dysbiosis
an imbalance of intestinal microbiota.

Dyskinesia
impaired control of voluntary movement. Dyskinesia is sometimes a side effect of long-term use of antipsychotic medications.

Dyslipidemia
a disorder of lipoprotein metabolism.

Glossary: E

Back to top

EAR
estimated average requirement; a nutrient intake value that is estimated to meet the requirement of half of the healthy individuals in a particular life stage and gender group.

Echocardiography
a diagnostic test that uses ultrasound to make images of the heart. It can be used to assess the health of the valves and chambers of the heart, as well as to measure cardiac output.

Eclampsia
seizures in a woman caused by pregnancy-induced hypertension; a significant cause of maternal mortality.

Ecologic study
an epidemiological study that examines the relationships between exposures and disease rates in a series of populations (e.g., different countries). Ecologic studies often rely on published statistics, such as food disappearance data or disease-specific death rates.

Edema
swelling; accumulation of excessive fluid in subcutaneous tissues (beneath the skin).

Eicosanoid
a chemical messenger derived from a 20-carbon polyunsaturated fatty acid, such as arachidonic acid and eicosapentaenoic acid. Eicosanoids play critical roles in immune and inflammatory responses.

Elastin
a flexible structural protein similar to collagen; elastin is found in the dermal layer of skin and other parts of the body.

Electrocardiogram (ECG)
a recording of the electrical activity of the heart, used to diagnose cardiac arrhythmias, myocardial ischemia and myocardial infarction.

Electroencephalogram (EEG)
a recording of the electrical activity of the brain, used to diagnose neurological conditions like seizure disorders (epilepsy).

Electrolytes
ionized (dissociated into positive and negative ions) salts in the body fluids. Major electrolytes in the body include sodium, potassium, magnesium, calcium, chloride, bicarbonate, and phosphate.

Electron
a stable atomic particle with a negative charge.

Electron transport chain
a group of electron carriers in mitochondria that transport electrons to and from each other in a sequence, in order to generate ATP.

Element
one of the 103 chemical substances that cannot be divided into simpler substances by chemical means. For example, hydrogen, magnesium, lead, and uranium are all chemical elements. Trace elements are chemical elements that are required in very small (trace) amounts in the diet to maintain health. For example, copper, selenium, and iodine are considered trace elements.

Emphysema
a chronic obstructive pulmonary (lung) disease, characterized by damage to the small air sacs (alveoli) and difficulty breathing. Damage to the alveoli decreases their elasticity and results in hyperinflation of the lungs, which impairs gas exchange. Smoking is the most common cause of emphysema.

Enamel
the hard, white, outermost layer of a tooth.

Enantiomer
either of two optical isomers that are mirror images of each other.

Encephalopathy
a disease of the brain that alters brain function.

Endocrine system
the glands and parts of glands that secrete hormones that integrate and control the body's metabolic activity. Endocrine glands include the pituitary, thyroid, parathyroids, adrenals, pancreas, ovaries, and testes.

Endocytosis
A type of cellular uptake that involves invagination of the cell membrane at the site of ligand binding followed by internalization of the substance inside a membrane-bound vesicle.

Endogenous
arising from within the body. Endogenous synthesis refers to the synthesis of a compound by the body.

Endometrium
the inner lining of the uterus.

Endothelium-dependent vasodilation
arterial vasodilation resulting from the production of nitric oxide in the vascular endothelium.

Endotoxin
toxins released by certain bacteria.

Enrichment
the addition of nutrients to replace losses that may occur in food processing.

Enterocyte
a cell that lines the luminal (inner) surface of the intestine.

Enzyme
a biological catalyst; that is, a substance that increases the speed of a chemical reaction without being changed in the overall process. Enzymes are vitally important to the regulation of the chemistry of cells and organisms.

Epidemiological study
a study examining disease occurrence in a human population.

Epidermis
the outer layers of skin above the dermis. The epidermis consists of overlapping layers of keratinocytes in various stages of development, eventually forming the barrier that protects underlying cell layers from the environment.

Epididymis
a system of tubules emerging from the testes, which serves as a storage site for sperm during their maturation.

Epilepsy
also known as seizure disorder. Individuals with epilepsy experience seizures, which are the result of uncontrolled electrical activity in the brain. A seizure may cause a physical convulsion, minor physical signs, thought disturbances, or a combination of symptoms.

Epithelium
layer of cells that lines a body cavity or covers an external surface of the body.

Erythema
reddening of the skin; often used as an indice of inflammation caused by ultraviolet exposure.

Erythrocyte
red blood cell.

Erythroid
relating to erythrocytes.

Erythropoiesis
the production of red blood cells.

Erythropoietin
a hormone produced by specialized cells in the kidneys that stimulates the bone marrow to increase the production of red blood cells. Recombinant erythropoietin is used to treat anemia in patients with end stage renal failure.

Esophagus
the portion of the gastrointestinal tract that connects the throat (pharynx) to the stomach.

Ester
the product of a reaction between a carboxylic acid and an alcohol that involves the elimination of water. For example a cholesterol ester is the product of a reaction between a fatty acid and cholesterol.

Estrogen
a hormone that binds to estrogen receptors in the nuclei of cells and promotes the transcription of estrogen-responsive genes. Endogenous estrogens are steroid hormones produced by body. Exogenous estrogens are synthetic or natural compounds that have estrogenic activity (i.e., bind the estrogen receptor and promote estrogen-responsive gene transcription).

Etiology
the causes or origin of a disease.

Euglycemia
normal blood glucose concentrations.

Excitotoxicity
the toxicity that results from the continuous stimulation of nerve cells by neurotransmitters.

Excretion
the elimination of wastes from blood or tissues.

Executive function
a set of mental processes that helps connect past experience with present action. Executive functions include planning, organizing, strategizing, remembering details, and managing time and space.

Extracellular fluid (ECF)
the volume of body fluid excluding that in cells. ECF includes the fluid in blood vessels (plasma) and fluid between cells (interstitial fluid).

Glossary: F

Back to top

Familial adenomatous polyposis
a hereditary syndrome characterized by the formation of many polyps in the colon and rectum, some of which may develop into colorectal cancer.

Fatty acid
an organic acid molecule consisting of a chain of carbon molecules and a carboxylic acid (-COOH) group. Fatty acids are found in fats, oils, and as components of a number of essential lipids, such as phospholipids and triglycerides. Fatty acids can be burned by the body for energy.

Femoral neck
a portion of the thighbone (femur). The femoral neck is found near the hip, at the base of the head of femur, which makes up the ball of the hip joint. Fractures of the femoral neck sometimes occur in individuals with osteoporosis.

Fetal macrosomia
a newborn of birth weight >4,000 grams (>8 pounds 13 ounces).

Fermentation
an anaerobic process that involves the breakdown of dietary components to yield energy.

Fibroblast
a cell that secretes extracellular matrix proteins, such as collagen, which give skin its structure. These cells are mostly found in the dermis and connective tissue.

Fibrocystic breast changes (FCC)
a benign (noncancerous) condition of the breasts, characterized by lumpiness and discomfort in one or both breasts.

First-pass metabolism
a phenomenon of drug metabolism whereby the concentration of a drug is greatly reduced before it reaches the systemic circulation due to action from the gastrointestinal tract and liver.

Food frequency questionnaire
a method of dietary assessment in which study participants are given a validated list of food and beverages and asked to report the frequency and portion size consumed over a given period of time.

Forced expiratory volume (FEV1)
the volume of air that can be expelled during the first second of a forced expiration. FEV1 is used to assess pulmonary (lung) function.

Fortification
the addition of nutrients to foods to prevent or correct a nutritional deficiency.

Fracture
a break in a bone or cartilage, often but not always the result of trauma.

Free radical
a very reactive atom or molecule typically possessing a single unpaired electron.

Fructosamine
describes a group of circulating proteins that have become irreversibly bound to glucose. Fructosamine assays provide information about blood glucose control two to three weeks prior to sample collection.

Fructose
a very sweet six-carbon sugar abundant in plants. Fructose is increasingly common in sweeteners such as high-fructose corn syrup.

Glossary: G

Back to top

Gallbladder
a small sac adjacent to the liver. The gallbladder stores bile, which is secreted by the liver, and releases it into the small intestine through the common bile duct.

Gallstones
crystals formed by the precipitation of cholesterol or bilirubin in the gallbladder. Gallstones may be asymptomatic (without symptoms) or they may result in inflammation and infection of the gallbladder.

Gastric
pertaining to the stomach.

Gastric mucosa
a mucus membrane lining of the interior of the stomach that protects the underlying stomach tissue.

Gastritis
inflammation of the lining of the stomach.

Gastroesophageal reflux disease (GERD)
a condition in which stomach contents, including acid, back up (reflux) into the esophagus, causing inflammation and damage to the esophagus. GERD can lead to scarring of the esophagus and may increase the risk of cancer of the esophagus in some patients.

Gastrointestinal
referring to or affecting the digestive tract, which includes the mouth, pharynx (throat), esophagus, stomach, and intestines.

Gene
a region of DNA that controls a specific hereditary characteristic, usually corresponding to a single protein.

Gene expression
the process by which the information coded in genes (DNA) is converted to proteins and other cellular structures. Expressed genes include those that are transcribed to mRNA and translated to protein, as well as those that are only transcribed to RNA (e.g., ribosomal and transfer RNAs).

Genome
all of the genetic information (encoded in DNA) possessed by an organism.

Genotype
the genetic makeup of an individual cell or organism.

Gestation
the period of time between fertilization and birth. In humans, normal gestation is about 40 weeks.

Gingiva
the soft tissue lining the mouth (i.e., gums).

Gingivitis
inflammation of the gingiva.

Glomerulus (plural glomeruli)
a tuft of capillaries that makes up part of the filtering unit of the kidney (nephron).

Gluconeogenesis
the production of glucose from non-carbohydrate precursors, such as amino acids (the building blocks of proteins).

Glucose
a six-carbon sugar which plays a major role in the generation of energy for living organisms.

Glucose tolerance
the ability of the body to maintain normal glucose levels when challenged with a carbohydrate load (see impaired glucose tolerance).

Glucoside
a glycoside that contains glucose as its carbohydrate (sugar) moiety.

Glutamate
an excitatory neurotransmitter. Under certain circumstances glutamate may become toxic to neurons. Glutamate excitotoxicity appears to play a role in nerve cell death in some neurodegenerative disorders.

Glutathione
a tripeptide consisting of glutamate, cysteine, and glycine. Glutathione is an endogenous, intracellular antioxidant and is also required for some phase II biotransformation reactions.

Glycated hemoglobin
glucose-bound hemoglobin. A test for glycated hemoglobin measures the percentage of hemoglobin that is glucose bound. Since glucose remains bound to hemoglobin for the life of a red blood cell (~120 days), glycated hemoglobin values reflect blood glucose control over the past four months.

Glycemic index (GI)
an index of the blood glucose-raising potential of the carbohydrate in different foods. The GI is calculated as the area under the blood glucose curve after a test food is eaten, divided by the corresponding area after a control food (glucose or white bread) is eaten. The value is multiplied by 100 to represent a percentage of the control food.

Glycemic load (GL)
an index that simultaneously describes the blood glucose-raising potential of the carbohydrate in a food and the quantity of carbohydrate in a food. The GL of a food is calculated by multiplying the GI by the amount of carbohydrate in grams provided by a food and dividing the total by 100.

Glycogen
a large polymer (repeating units) of glucose molecules, used to store energy in cells, especially muscle and liver cells.

Glycolysis
the metabolic pathway in the cytosol that degrades glucose, producing energy in the form of ATP.

Glycoside
a compound containing a sugar molecule that can be cleaved by hydrolysis to a sugar and a nonsugar component (aglycone).

Goiter
enlargement of the thyroid gland. Goiter is one of the earliest and most visible signs of iodine deficiency. The thyroid enlarges in response to persistent stimulation by TSH. In mild iodine deficiency, this adaptive response may be enough to provide the body with sufficient thyroid hormone. However, more severe cases of iodine deficiency result in hypothyroidism. Thyroid enlargement may also be caused by factors other than iodine deficiency, especially in iodine sufficient countries, such as the US.

Goitrogen
a substance that induces goiter formation by interfering with thyroid hormone production or utilization.

Gout
a condition characterized by abnormally high blood levels of uric acid (urate). Urate crystals may form in joints, resulting in inflammation and pain. Urate crystals may also form in the kidney and urinary tract, resulting in kidney stones. The tendency to develop elevated blood uric acid levels and gout is often inherited.

Granular layer
the layer of the epidermis below the stratum corneum.

Gray matter
the darker-colored tissue in the central nervous system that contains mostly cell bodies and dendrites.

GTP
guanosine triphosphate. A high-energy molecule, required for a number of biochemical reactions, including nucleic acid and protein synthesis (formation).

Glossary: H

Back to top

Haplotype
a set of DNA variations (polymorphisms) at adjacent locations on a chromosome; these DNA variations are inherited together.

Hartnup disease
a genetic disorder resulting in defective absorption of the amino acid, tryptophan.

HDL
high-density lipoproteins. HDL transport cholesterol from the tissues to the liver where it can be eliminated in bile. HDL-cholesterol is considered "good cholesterol," because higher blood levels of HDL-cholesterol are associated with lower risk of cardiovascular disease.

Hematocrit
the percentage of red blood cells in whole blood.

Hematology
the branch of medicine that studies the nature, function, disorders, and diseases of the blood, spleen, and lymph glands.

Heme
compounds of iron complexed in a characteristic ring structure known as a porphyrin ring.

Hemodialysis
the process of removing blood from an artery, removing waste products from the blood through dialysis, and returning blood to the body through a vein. Hemodialysis is used to treat end-stage renal failure.

Hemoglobin
the oxygen-carrying pigment in red blood cells.

Hemoglobin A1c
the main fraction of glycated (glucose-bound) hemoglobin. Since glucose remains bound to hemoglobin for the life of a red blood cell (~120 days), hemoglobin A1C values reflect blood glucose control over the past four months.

Hemolysis
rupture of red blood cells.

Hemolytic anemia
anemia resulting from hemolysis.

Hemorrhage
excessive or uncontrolled bleeding.

Hemorrhagic stroke
a stroke that occurs when a blood vessel ruptures and bleeds into the brain.

Hemorrhoids
dilated or enlarged veins of the anus and lower rectum.

Hemostasis
the arrest of bleeding.

Hepatic
relating to the liver.

Hepatic encephalopathy
a spectrum of neuropsychiatric signs or symptoms in individuals with acute or chronic liver disease.

Hepatitis
literally, inflammation of the liver. Hepatitis caused by a virus is known as viral hepatitis. Other causes of hepatitis include toxic chemicals and alcohol abuse.

Hepatocellular carcinoma
the most common type of primary liver cancer.

Hepatocyte
a parenchymal cell of the liver.

Hepatomegaly
an abnormally enlarged liver.

Hereditary hemochromatosis
a genetic disorder that results in iron overload despite normal dietary intake of iron.

Hereditary spherocytosis
a hereditary form of anemia characterized by abnormally shaped red blood cells which are spherical and abnormally fragile. The increased fragility of these red blood cells leads to hemolytic anemia (anemia caused by the rupture of red blood cells).

Heterodimer
a dimer or complex of two different molecules, usually proteins.

Heterogeneity
variability in study design and outcomes; the quality of being diverse and not comparable.

Heterozygous
possessing two different forms (alleles) of a specific gene.

Histology
the study of cells and tissues at the microscopic level.

Histone
protein that binds to DNA and packages it into compact structures to form nucleosomes.

HIV
human immunodeficiency virus; the virus that causes AIDS.

Homeostasis
a state of balance.

Homocysteine
a sulfur-containing amino acid, which is an intermediate in the metabolism of another sulfur-containing amino acid, methionine. Elevated homocysteine levels in the blood have been associated with increased risk of cardiovascular disease.

Homodimer
a dimer or complex of two of the same molecule, usually a protein.

Homologous
having the same appearance, structure, or evolutionary origin.

Homozygous
possessing two identical forms (alleles) of a specific gene.

Hormone
a chemical released by a gland or a tissue, which affects or regulates the activity of specific cells or organs. Complex bodily functions, such as growth and sexual development, are regulated by hormones.

Hot flushes
sensations of heat in the skin, particularly the face, neck, and chest; also known as hot flashes. Hot flushes are most often related to declining estrogen levels during the perimenopause (period surrounding menopause).

Human papilloma virus (HPV)
a group of viruses that may cause papillomas (growths or warts) on the skin or other parts of the body, including the genitals and the larynx (voice box). Infection with particular strains of HPV is associated with increased risk of cervical cancer.

Huntington's disease
an inherited degenerative disorder of the brain. Its symptoms include movement disorders and impaired cognitive function. Symptoms of Huntington's disease, previously known as Huntington's chorea, typically develop in the fourth decade of life and progressively deteriorate over time.

Hydrolysis
cleavage of a chemical bond by the addition of water. In hydrolysis reactions, a large compound may be broken down into smaller compounds when a molecule of water is added.

Hydrophilic
a molecule that has a high affinity for water and will readily dissolve in water.

Hydrophobic (lipophilic)
a molecule that repels water and thus will not dissolve in water.

Hydroxyapatite
a calcium phosphate salt. Hydroxyapatite is the main mineral component of bone and teeth and is what gives them their rigidity.

Hydroxylation
a chemical reaction involving the addition of a hydroxyl (-OH) group to a compound.

Hyperglycemia
an abnormally high blood glucose concentration; symptoms include increased thirst, increased urination, and general fatigue.

Hyperhomocysteinemia
abnormally elevated blood levels of homocysteine; associated with increased risk of cardiovascular disease.

Hyperhomocysteinuria
excessively high levels of plasma homocysteine.

Hyperkeratosis
irregular thickening of the stratum corneum due to increased number of corneocyte layers.

Hyperlipidemia
an abnormally high concentration of lipids in the blood.

Hypermetallation
refers to increased interactions between β-amyloid peptides and copper in Alzheimer's disease.

Hyperostosis
excessive growth of bone tissue.

Hyperparathyroidism
excess secretion of parathyroid hormone by the parathyroid glands resulting in the disturbance of calcium metabolism. Symptoms may include increased blood levels of calcium (hypercalcemia), decreased blood levels of phosphorus, loss of calcium from bone, and kidney stone formation.

Hyperplasia
excessive cell growth.

Hypertension
high blood pressure. According to the 2017 Clinical Practice Guidelines, hypertension is defined as a systolic blood pressure of 130 mm Hg or higher or a diastolic blood pressure of 80 mm Hg or higher.

Hyperthyroidism
an excess of thyroid hormone which may result from an overactive thyroid gland or nodule, or from taking too much thyroid hormone.

Hypertrophy
the enlargement of a tissue or organ due to an increase in the size of its cells.

Hypoglycemia
an abnormally low blood glucose concentration. Symptoms may include nausea, sweating, weakness, faintness, confusion hallucinations, headache, loss of consciousness, convulsions, or coma.

Hypoparathyroidism
a deficiency of parathyroid hormone, which may be characterized by low blood calcium levels (hypocalcemia).

Hypothalamus
an area at the base of the brain that regulates bodily functions, such as body temperature, hunger, and thirst.

Hypothesis
an educated guess or proposition that is advanced as a basis for further investigation. A hypothesis must be subjected to an experimental test to determine its validity.

Hypothyroidism
a deficiency of thyroid hormone that is normally made by the thyroid gland, located in the front of the neck.

Glossary: I

Back to top

Idiopathic
of unknown cause.

Ileostomy
a surgically created connection between the ileum (part of the small intestine) and an opening in the abdominal wall (stoma) that allows for the evacuation of feces when a portion of the bowel has been removed.

Ileum
the third and final section of the small intestine.

Impaired glucose tolerance
a metabolic state between normal glucose regulation and overt diabetes. Impaired glucose tolerance is defined medically as a plasma glucose concentration between 140 and 199 mg/dL (7.8-11.0 mmol) two hours after the ingestion of 75 g of glucose during an oral glucose tolerance test.

Incontinence
inability to control the evacuation of urine or feces.

Induction
initiation of or increase in the expression of a gene in response to a physical or chemical stimulus (inducer).

Inflammation
a response to injury or infection, characterized by redness, heat, swelling, and pain. Physiologically, the inflammatory response involves a complex series of events, leading to the migration of white blood cells to the inflamed area.

Inflammatory bowel disease
a group of autoimmune diseases that affect the small and large intestines.

Insoluble
not dissolvable. With respect to bioavailability, certain substances form insoluble complexes that cannot be dissolved in digestive secretions, and therefore cannot be absorbed by the digestive tract.

Insulin
a peptide hormone secreted by the β-cells of the pancreas required for normal glucose metabolism.

Insulin resistance
diminished responsiveness to insulin.

Insulin sensitivity
the ability of tissues to respond to insulin.

Intermittent claudication
a condition characterized by leg pain or weakness on walking that diminishes or resolves with rest. It is usually associated with peripheral arterial disease.

International normalized ratio (INR)
the preferred method for reporting prothrombin time, a measure of coagulation status that may be used to evaluate the therapeutic efficacy of anticoagulants, such as warfarin. The INR is

a method for standardizing prothrombin time results so as to minimize variability between laboratories.

Intervention trial
an experimental study (usually a clinical trial) used to test the effect of a treatment or intervention on a health- or disease-related outcome.

Intestinal microbiota
the collection of microbial species that live specifically in the lower gastrointestinal tract (colon).

Intracellular fluid (ICF)
the volume of fluid inside cells.

Intraperitoneal (ip) injection
injection into the peritoneum.

Intravenous
within a vein.

Inverse association
a relationship between two variables in which they move in opposite directions.

In vitro
literally "in glass," referring to a test or research done in the test tube, outside a living organism.

In vivo
"inside a living organism." An in vivo assay evaluates a biological process occurring inside the body.

Ion
an atom or group of atoms that carries a positive or negative electric charge as a result of having lost or gained one or more electrons.

Ion channel
a protein embedded in a cell membrane that serves as a crossing point for the regulated transfer of an ion or a group of ions across the membrane.

Ischemia
a state of insufficient blood flow to a tissue.

Ischemic stroke
a stroke resulting from insufficient blood flow to an area of the brain, which may occur when a blood vessel supplying the brain becomes obstructed by a clot.

Isocaloric
having the same caloric density.

Isomer
one of two or more compounds that has the same number and kind of atoms but differs in the way the atoms are arranged.

Isotope
a different form of the same chemical element. Isotopes have the same number of protons but different numbers of neutrons.

Glossary: J, K

Back to top

Jaundice
a yellowish staining of the skin and whites of the eyes due to increased bilirubin (a bile pigment) levels in the blood. Jaundice can be an indicator of red blood cells rupturing (hemolysis), or disease of the liver or gallbladder.

Keratinization
the process of cell differentiation of a keratinocyte through the different layers of the epidermis. At the end of keratinization, the cell is wider and flatter and attached to its neighboring cells by a variety of protein and lipid attachments.

Keratinocyte
primary cell type of the epidermis; these cells produce the structural protein keratin, which comprise the epidermal barrier.

Ketone bodies
any of three acidic chemicals (acetate, acetoacetate, and β-hydroxybutyrate). Ketone bodies may accumulate in the blood (ketosis) when the body has inadequate glucose to use for energy and must increase the use of fat for fuel. Ketone bodies are acidic, and very high levels in the blood are toxic and may result in ketoacidosis.

Kidney stones
solid masses resulting from the crystallization of minerals and other compounds found in urine. Common types of kidney stones include those composed of calcium oxalate, calcium phosphate and urate. Kidney stones may form in the kidneys, ureters, or urinary bladder.

Glossary: L

Back to top

Langerhan cell
an antigen-presenting cell involved in epidermal immunity.

Laryngospasm
spasm that causes closure of the larynx, interfering with breathing.

Larynx
the area of the throat (pharynx) that contains the vocal cords.

LDL
low-density lipoprotein. LDLs transport cholesterol from the liver to the tissues of the body. Elevated serum LDL-cholesterol is associated with increased cardiovascular disease risk.

Left ventricular hypertrophy (LVH)
abnormal thickening of the wall of the left ventricle (lower chamber) of the heart muscle. The ventricles have muscular walls in order to pump blood from the heart through the arteries, but LVH occurs when the ventricle must pump against abnormally high volume or pressure loads. LVH may accompany congestive heart failure (CHF).

Legumes
members of the large family of plants known as leguminosae. In this context the term refers to the fruit or seeds of leguminous plants (e.g., peas and beans) that are used for food.

Lens
the transparent structure inside the eye that focuses light rays onto the retina (the nerve cells at the back of the eye).

Leptin
hormone secreted by adipose tissue that helps to regulate of food intake, body weight, and energy homeostasis.

Leptin resistance
resistance to the action of leptin.

Leukemia
an acute or chronic form of cancer that involves the blood-forming organs. Leukemia is characterized by an abnormal increase in the number of white blood cells in the tissues of the body, with or without a corresponding increase of those in the circulating blood, and is classified according to the type of white blood cell most prominently involved.

Leukocyte
white blood cell. Leukocytes are part of the immune system. Monocytes, lymphocytes, neutrophils, basophils, and eosinophils are different types of leukocytes.

Leukotriene
cell-signaling molecule involved in inflammation. Lipoxygenases catalyze the formation of leukotrienes from eicosanoids, such as arachidonic acid and eicosapentaenoic acid (EPA).

Ligand
a substance that binds to another molecule, forming a complex.

Lipid peroxidation
the process by which lipids are oxidatively modified; so named because lipid hydroperoxides are formed in the process.

Lipid
a chemical term for fat. Lipids found in the human body include fatty acids, phospholipids, and triglycerides.

Lipogenesis
the production of fatty acids.

Lipoic acid
a cofactor, essential for the oxidation of α-keto acids, such as pyruvate, in metabolism.

Lipolysis
the breakdown of lipids by hydrolysis.

Lipoprotein(a) [Lp(a)]
a lipoprotein particle in which the protein (apolipoprotein B-100) is chemically linked to another protein apolipoprotein(a). Increased blood levels of Lp(a) are associated with an increased risk of cardiovascular disease.

Lipoprotein
particle composed of lipids and protein that allows for the transport of lipids through the bloodstream. A lipoprotein particle is composed of an outer layer of phospholipids, which renders it soluble in water, and a hydrophobic core that contains triglycerides and cholesterol esters. Different types of lipoproteins are distinguished by their surface proteins (apoproteins), their size, and the types and amounts of lipids they contain.

Lumbar spine
the portion of the spine between the chest (thorax) and the pelvis. It is commonly referred to as the small of the back.

Lumen
the channel within a tube such as a blood vessel or the intestine.

Lupus
see systemic lupus erythematosus (SLE).

Lymphocyte
leukocyte (white blood cells) that plays important roles in the immune system. T lymphocytes (T cells) differentiate into cells that can kill infected cells or activate other cells in the immune system. B lymphocytes (B cells) differentiate into cells that produce antibodies.

Lysosome
a cellular organelle containing hydrolytic enzymes specialized for breaking down cellular debris. Lysosomal enzymes are separated from the rest of the cell by a lysosomal membrane and function optimally at an acidic pH.

Glossary: M

Back to top

Macrocytic anemia
low red blood cell count, characterized by the presence in the blood of larger than normal red blood cells.

Macronutrient
nutrients required in relatively large amounts; macronutrients include carbohydrates, proteins, and lipids.

Macrophage
white blood cell that engulfs and degrades pathogens (bacteria) and cellular debris. Macrophages are activated or transformed monocytes.

Macula
a small area of the retina where vision is the sharpest. The macula is located in the center of the retina and provides central vision.

Magnetic Resonance Imaging (MRI)
a special imaging technique that uses a powerful magnet and a computer to provide clear images of soft tissues. Tissues that are well-visualized using MRI include the brain and spinal cord, abdomen, and joints.

Malabsorption syndrome
a disease or condition that results in poor absorption of nutrients from food.

Malaria
an infectious disease caused by parasitic microorganisms called plasmodia. Malaria can be spread among humans through the sting of certain types of mosquitos (Anopheles) or by a contaminated needle or transfusion. Malaria is a major health problem in the tropics and subtropics, affecting over 200 million people worldwide.

Malignant
cancerous.

Matrix metalloproteinase (MMP)
a proteolytic enzyme that degrades extracellular matrix proteins, such as collagen and elastin.

M cells
membranous or microfold cells; specialized cells in the intestinal epithelium that internalize pathogenic microorganisms to the gut-associated lymphoid tissue.

Measurement error
the difference between a measured value and its true value.

Megaloblastic anemia
low red blood cell count, characterized by the presence in the blood of large, immature, nucleated cells (megaloblasts) that are forerunners of red blood cells. Red blood cells, when mature, have no nucleus.

Melanin
a dark brown pigment found in the skin.

Melanocyte
a pigment-containing cell of the epidermis. The pigment, melanin, absorbs ultraviolet light and protects the skin from damage. Unlike keratinocytes, melanocytes are not shed over time.

Membrane potential
the electrical potential difference across a membrane. The membrane potential is a result of the concentration differences between potassium and sodium across cell membranes, which are maintained by ion pumps. A large proportion of the body's resting energy expenditure is devoted to maintaining the membrane potential, which is critical for nerve impulse transmission, muscle contraction, heart function, and the transport of nutrients and metabolites in and out of cells.

Menarche
the first occurrence of menstruation.

Mendelian randomization study
genetic study conducted to assess whether genetic determinants of a risk factor are related to clinical outcomes.

Menstruation
the cyclic loss of blood by a woman from her uterus (womb) when she is not pregnant. Menstruation generally occurs every four weeks after a woman has reached sexual maturity and prior to menopause.

Meta-analysis
a statistical technique used to combine the results from different studies to obtain a quantitative estimate of the overall effect of a particular intervention or exposure on a defined outcome.

Metabolic syndrome
a combination of medical conditions that places one at risk for cardiovascular disease and type 2 diabetes. (Metabolic syndrome is also called metabolic syndrome X, syndrome X, and insulin resistance syndrome.) Diagnostic criteria include the presence of three or more of the following conditions:

- Abdominal obesity (waist circumference: ≥40 inches [102 cm] for men, ≥35 inches [88 cm] for women)
- Elevated triglycerides (≥150 mg/dL or on drug treatment for elevated triglycerides)
- High blood pressure (≥130 mm Hg for systolic blood pressure and/or ≥85 mm Hg for diastolic blood pressure, or taking anti-hypertensive drugs)
- Glucose intolerance/insulin resistance (fasting blood glucose ≥100 mg/dL, or on drug treatment for elevated glucose)
- Decreased HDL cholesterol (<40 mg/dL for men and <50 mg/dL for women, or on drug treatment for low HDL cholesterol)

Metabolism
the sum of the processes (reactions) by which a substance is assimilated and incorporated into the body or detoxified and excreted from the body.

Metabolite
a compound derived from the metabolism of another compound is said to be a metabolite of that compound.

Metastasize
to spread from one part of the body to another. Cancer is said to metastasize when it spreads from the primary site of origin to a distant anatomical site.

Methionine
a sulfur containing amino acid, required for protein synthesis and other vital metabolic processes. It can be obtained through the diet in protein or synthesized from homocysteine.

Methylation
a biochemical reaction resulting in the addition of a methyl group (-CH$_3$) to another molecule.

Micelle
an aggregate or cluster of amphipathic molecules in water. Amphipathic molecules have a polar or hydrophilic end and a nonpolar or hydrophobic end. In micelles, amphipathic molecules orient with their hydrophobic ends in the interior and their hydrophilic ends on the exterior surface, exposed to water.

Micronutrient
a nutrient required by the body in small amounts, such as a vitamin or a mineral.

MicroRNA
small non-coding RNA involved in the regulation of gene expression.

Microtia
underdevelopment of the external ear.

Migraine headache
a type of headache thought to be related to abnormal sensitivity of blood vessels (arteries) in the brain to various triggers resulting in rapid changes in the artery size due to spasm (constriction). Other arteries in the brain and scalp then open (dilate), and throbbing pain is perceived in the head. The tendency toward migraine appears to involve serotonin, a neurotransmitter that can trigger the release of vasoactive substances in the blood vessels.

Mineral
nutritionally significant element. Elements are composed of only one kind of atom. Minerals are inorganic, i.e., they do not contain carbon as do vitamins and other organic compounds.

Minimal Erythemal Dose (MED)
the lowest dose of ultraviolet radiation (UVR) that will produce a detectable erythema 24 hours after UVR exposure.

Mitochondria
energy-producing structures within cells. Mitochondria possess two sets of membranes: a smooth continuous outer membrane and an inner membrane arranged in folds. Among other critical functions, mitochondria convert nutrients into energy via the electron transport chain.

Mitosis
the process of cell division.

mm Hg
millimeters of mercury. The unit of measure for blood pressure.

Moiety
a portion of something, such as a functional group of a molecule.

Mole
the fundamental unit for measuring chemical compounds (abbreviated mol). One mole equals the molecular weight of a compound in grams. The number of molecules in a mole is equal to 6.02 x 10^{23} (Avogadro's number).

Molecular chaperone
a class of proteins that facilitates in the folding and assembly of other proteins.

Monocyte
white blood cell that is the precursor to a macrophage.

Monomer
a molecule that can be chemically bound as a unit of a polymer.

Monotherapy
the use of a single medication to treat a condition.

Monounsaturated fatty acid
a fatty acid with only one double bond between carbon atoms.

mRNA
short for messenger ribonucleic acid (RNA). These molecules are the ‘message' that encodes the proteins produced in cells. Increases or decreases in mRNA levels will alter protein production in cells.

Mucin
a glycoprotein that lubricates and protects body surfaces.

Mucocutaneous
relating to the mucous membranes of the skin.

Multifactorial
refers to diseases or conditions that are the result of interactions between multiple genetic and environmental factors.

Multiple sclerosis (MS)
an autoimmune disorder in which the myelin sheaths of nerves in the brain and spinal cord are damaged, resulting in progressive neurological symptoms.

Mutagen
an agent that can induce mutation.

Mutation
a change in a gene; in other words, a change in the sequence of base-pairs in the DNA that makes up a gene. Mutations in a gene may or may not result in an altered gene product.

Myelin
the fatty substance that covers myelinated nerves. Myelin is a layered tissue surrounding the axons or nerve fibers. This sheath acts as a conduit in an electrical system, allowing rapid and efficient transmission of nerve impulses.

Myelination
the formation of the myelin sheath around a nerve fiber.

Myeloid
derived from bone marrow.

Myocardial infarction (MI)
death (necrosis) of heart muscle tissue due to an interruption in its blood supply. Commonly known as a heart attack, an MI usually results from the obstruction of a coronary artery by a clot in people who have coronary atherosclerosis.

Myocardial stunning
a temporary dysfunction of the cardiac myocardium (contractile abormality) following ischemia and reperfusion.

Myocarditis
an inflammation of the heart muscle.

Myocyte
muscle cell.

Myoglobin
a heme-containing pigment in muscle cells that binds and stores oxygen.

Myopathy
any disease of muscle.

Glossary: N

Back to top

Natural killer (NK) cells
cytotoxic lymphocytes important for the innate immune response that kills pathogens. NK cells also have important roles in killing cancer cells.

Necrosis
unprogrammed cell death, in which cells break open and release their contents, promoting inflammation. Necrotic cell death may be the result of injury, infection, or infarction.

Neoplasm
a term referring to a rapid and abnormal growth of tissue. Neoplasms can be benign or malignant.

Nephropathy
kidney damage or disease.

Nerve impulse
the electrochemical signal transmitted in the cell membrane of a neuron or muscle cell. Also called action potential.

Nested case-control study
a case-control study within a cohort study; cases of a disease that occur in a defined cohort are identified, and a specified number of matched controls is then selected from the larger cohort for comparison.

Neural Tube Defect (NTD)
a birth defect caused by abnormal development of the neural tube, the structure which gives rise to the central nervous system. Neural tube defects include anencephaly and spina bifida.

Neurodegenerative disease
disease resulting from the degeneration or deterioration of nerve cells (neurons). Alzheimer's disease and Parkinson's disease are neurodegenerative diseases.

Neurogenesis
the formation and development of nerves, nerve tissue, or the nervous system.

Neurologic
or neurological; involving nerves or the nervous system (brain, spinal cord, and all sensory and motor nerves).

Neuron
cell of the nervous system that conducts nerve impulses. Also called nerve cell.

Neuropathy
nerve damage or disease.

Neurotoxic
toxic or damaging to nervous tissue (brain and peripheral nerves).

Neurotransmitter
a chemical that is released from a nerve cell and results in the transmission of an impulse to another nerve cell or organ (e.g., a muscle). Acetylcholine, dopamine, norepinephrine, and serotonin are neurotransmitters.

Neutrophil
white blood cell that internalizes and destroys pathogens, such as bacteria. Neutrophils are also called polymorphonuclear leukocytes because they are white blood cells with multi-lobed nuclei.

NIH
US National Institutes of Health. Administered under the US Department of Health and Human Services (HHS), the NIH are more than 20 separate institutes and centers devoted to medical research.

Nitric oxide
a gaseous signaling molecule synthesized from the amino acid arginine by enzymes called nitric oxide synthases. In the vascular endothelium, nitric oxide promotes arterial vasodilation.

Normotensive
having normal blood pressure, i.e., a systolic blood pressure <120 mm Hg and a diastolic blood pressure <80 mm Hg.

Nucleic acid
DNA (deoxyribonucleic acid) and RNA (ribonucleic acid); long polymer of nucleotides.

Nucleosome
repeating unit of chromatin that consists of DNA that is coiled around histones.

Nucleoside
a compound composed of a nitrogen-containing base (adenine, guanine, cytosine, uracil, or thymine) linked to either ribose or deoxyribose.

Nucleotide
subunit of nucleic acids. Nucleotides are composed of a nitrogen-containing base (adenine, guanine, cytosine, uracil, or thymine), a five-carbon sugar (ribose or deoxyribose), and one or more phosphate groups.

Nucleus
a membrane-bound cellular organelle, which contains DNA organized into chromosomes.

Glossary: O

Back to top

Obesity
a condition of increased body fat; defined as a body mass index (BMI) ≥30 for adults.

Observational study
a study in which no experimental intervention or treatment is applied. Participants are simply observed over time.

Ocular
relating to the eye.

Odds ratio (OR)
a measure of association comparing the odds of an outcome in the exposed group to the odds of an outcome in the non-exposed (control) group. The OR is an approximation of the relative risk.

Omega-3 index
the amount of eicosapentaenoic acid (EPA) plus docosahexaenoic acid (DHA) in red blood cell membranes expressed as the percent of total red blood cell membrane fatty acids.

Oncology
the field of medicine dealing with cancer and tumors.

One-carbon unit
a biochemical term for functional groups containing only one carbon in addition to other atoms. One-carbon units transferred by folate coenzymes include methyl (-CH$_3$), methylene (-CH$_2$-), formyl (-CH=O), formimino (-CH=NH), and methenyl (-CH=). Many biosynthetic reactions involve the addition of a one-carbon unit to a precursor molecule.

Open-label trial
a clinical trial in which the investigators and participants are aware of the treatment (i.e., it is not double-blind).

Optimum health
in addition to freedom from disease, the ability of an individual to function physically and mentally at his or her best.

Oral (po) administration
administration of a substance by mouth.

Organelle
a specialized component of a cell, such as the mitochondrian or lysosome, so named because they are analogous to organs.

Organic
refers to carbon-containing compounds, generally synthesized by living organisms.

Oropharynx
a term used to describe the mouth and throat.

Osteoarthritis
a degenerative joint condition that is characterized by the breakdown of articular cartilage (cartilage within the joint).

Osteoblast
bone cell that is responsible for the formation of new bone mineral in the bone remodeling process.

Osteoclast
bone cell that is responsible for the breakdown or resorption of bone in the bone remodeling process.

Osteocyte
a type of bone cell formed from an osteoblast once it becomes embedded deep within the organic matrix.

Osteomalacia
a disease of adults that is characterized by softening of the bones due to loss of bone mineral. Osteomalacia is characteristic of vitamin D deficiency in adults, while children with vitamin D deficiency suffer from rickets.

Osteonecrosis
death of bone tissue.

Osteopenia
a condition of low bone mass clinically defined as having a T-score one to 2.5 standard deviations (SD) below that of the average young adult (30 years of age) female.

Osteoporosis
a condition of increased bone fragility and susceptibility to bone fracture due to a loss of bone mineral density (BMD)

Overnutrition
a form of malnutrition where nutrients are supplied in excess of the body's needs.

Oxidant
reactive oxygen species.

Oxidation
a chemical reaction that removes electrons from an atom or molecule.

Oxidative damage
damage to cells caused by reactive oxygen species.

Oxidative stress
a condition, in which the effects of pro-oxidants (e.g., free radicals, reactive oxygen and reactive nitrogen species) exceed the ability of antioxidant systems to neutralize them.

Glossary: P,Q

Back to top

Pancreas
a small organ located behind the stomach and connected to the duodenum (part of the small intestine). The pancreas synthesizes enzymes that help digest food in the small intestine and hormones, including insulin, that regulate blood glucose levels.

Papillary dermis
the uppermost layer of the dermis.

Parathyroid glands
glands located behind the thyroid gland in the neck. The parathyroid glands secrete a hormone called parathyroid thormone (PTH) that is critical to calcium and phosphorus metabolism.

Parenteral nutrition
intravenous administration of nutrition.

Parkinson's disease
a disease of the nervous system caused by degeneration of a part of the brain called the basal ganglia, as well as by low production of the neurotransmitter dopamine. Symptoms include muscle rigidity, tremors, and slow voluntary movement.

Pathogen
disease-causing agents, such as viruses or bacteria.

Pathogenesis
the biological mechanisms underlying the development of a disease.

Pathology
the branch of medicine that studies the causes and effects of disease.

Peptic ulcer disease
a disease characterized by ulcers or breakdown of the inner lining of the stomach or duodenum. Common risk factors for peptic ulcer disease include the use of nonsteroidal anti-inflammatory drugs (NSAIDs) and infection with *Helicobacter pylori*.

Peptide
a chain of amino acids. A protein is made up of one or more peptides.

Peptide hormone
a hormone that is a protein, as opposed to a steroid hormone, which is made from cholesterol. Insulin is an example of a peptide hormone.

Percutaneous
through the skin.

Percutaneous transluminal coronary angioplasty (PTCA)
a nonsurgical technique, in which a balloon catheter is inserted into a peripheral artery and passed into an occluded coronary artery, where the balloon is inflated to dilate the artery.

Perinatal
the period of time just before and after birth (varyingly defined as the time period starting between 20 to 28 weeks' gestation and ending one to four weeks after birth).

Periodontium
the tissues and gingiva surrounding the teeth.

Peripheral arterial disease
atherosclerosis of the arteries of the extremities.

Peripheral neuropathy
a disease or degenerative state affecting the nerves of the extremities (arms and legs). Symptoms may include numbness, pain, and muscle weakness.

Peripheral vascular disease
atherosclerosis of the vessels of the extremities, which may result in insufficient blood flow or pain in the affected limb, particularly during exercise.

Peritoneal dialysis
a procedure in which a special dialysis solution is introduced through a tube in the peritoneum. The dialysis solution pulls wastes and extra fluid from the body when the dialysis solution is drained through the same tube. The most common form is called continuous ambulatory peritoneal dialysis and can be performed at home without a machine.

Peritoneum
a membrane that lines the walls of the abdominal cavity.

Pernicious anemia
the end stage of an autoimmune inflammation of the stomach, resulting in destruction of stomach cells by one's own antibodies. Progressive destruction of the cells that line the stomach cause decreased secretion of acid and enzymes required to release food bound vitamin B$_{12}$. Antibodies to intrinsic factor (IF) bind to IF preventing formation of the IF-B$_{12}$ complex, further inhibiting vitamin B$_{12}$ absorption.

PET scan
positron emission tomography scan. A diagnostic imaging technique that uses a sophisticated camera and computer to produce images of how a person's body is functioning. A PET scan shows the difference between healthy and abnormally functioning tissues.

pH
a measure of acidity or alkalinity.

Phagocyte
a specialized cell, such as a macrophage, that engulfs and digests invading microorganisms through the process of phagocytosis.

Phagocytosis
process by which phagocytes engulf and digest invading microorganisms and foreign particles.

Phagosome
an intracellular vesicle containing the foreign material engulfed by the phagocyte.

Pharmacokinetics
the study of the absorption, distribution, metabolism, and elimination of drugs and other compounds.

Pharmacological dose
the dose or intake level of a nutrient many times the level associated with the prevention of deficiency or the maintenance of health. A pharmacologic dose is generally associated with the treatment of a disease state and considered to be a dose at least 10 times greater than that needed to prevent deficiency.

Phase I clinical trial
a clinical trial in a small group of people aimed at determining bioavailability, optimal dose, safety, and early evidence of the efficacy of a new therapy.

Phase II clinical trial
a clinical trial designed to investigate the effectiveness of a new therapy in larger numbers of people and to further evaluate short-term side effects and safety of the new therapy.

Phase III clinical trial
once a drug or treatment has been shown to be efficacious and safe in phase I and II clinical trials, a large, phase III clinical trial must be conducted before the drug or treatment receives formal FDA approval.

Phenolic compounds
a class of chemical compounds consisting of a hydroxyl functional group (-OH) attached to an aromatic hydrocarbon group. An aromatic hydrocarbon has a ring structure like that of benzene. Polyphenolic compounds contain more than one phenolic group.

Phenylketonuria (PKU)
an inherited disorder resulting in the inability to process the amino acid, phenylananine. If not treated, the disorder may result in mental retardation. Treatment is a diet low in phenylalanine. Newborns are screened for PKU, in order to determine the need for treatment before brain damage occurs.

Phlebotomy
the removal of blood from a vein. Phlebotomy may be used to obtain blood for diagnostic tests or to treat certain conditions, for example, iron overload in hemochromatosis.

Phospholipid
lipid in which phosphoric acid, as well as fatty acids, are attached to a glycerol backbone. Phospholipids are important structural components of cell membranes.

Phosphorylation
the creation of a phosphate derivative of an organic molecule. This is usually achieved by transferring a phosphate group (-PO$_4$) from ATP to another molecule.

Photodamage
skin damage induced by ultraviolet (UV) light that is absorbed in an uncontrolled manner by molecules in the body. Depending on the dose, UV light can cause cell death and an inflammatory response.

Physiologic dose
the dose or intake level of a nutrient associated with the prevention of deficiency or the maintenance of health. A physiologic dose of a nutrient is not generally greater than that which could be achieved through a conscientious diet, as opposed to the use of supplements.

Phytochemical
biologically active, non-nutrient compound synthesized by plants.

Phytoestrogen
a plant-derived compound with estrogenic activity.

Pigment
a compound that gives a plant or animal cell color by the selective absorption of different wavelengths of light.

Pilosebaceous unit
hair follicles in the skin that are associated with a sebaceous gland.

Pilot study
a preliminary study conducted on a small scale in order to prepare for a larger study.

Pituitary gland
a small oval gland located at the base of the brain that secretes hormones regulating growth and metabolism. The pituitary gland is divided into two separate glands, the anterior and posterior pituitary glands, which each secrete different hormones.

Placebo
an inert treatment that is given to a control group while the experimental group is given the active treatment. Placebo-controlled studies are conducted to make sure that the results are due to the experimental treatment, rather than another factor associated with participating in the study.

Placenta
the organ that connects the fetus to the pregnant woman's uterus, allowing for the exchange of oxygen, carbon dioxide, nutrients, and waste between woman and fetus.

Placental abruption
premature separation of the placenta from the wall of the uterus. Abruption is a potentially serious problem both for the woman and fetus.

Plasma
whole blood without blood cells; that is, red blood cells and white blood cells have been removed. Plasma is separated from blood cells using a centrifuge. Unlike serum, plasma retains clotting factors because it is obtained from blood that is not allowed to clot.

Platelet
irregularly shaped cell fragments that assist in blood clotting.

Pneumonia
a disease of the lungs characterized by inflammation and accumulation of fluid in the lungs. Pneumonia may be caused by infectious agents (e.g., viruses or bacteria) or by inhalation of certain irritants.

Polymer
a large molecule formed by combining many similar smaller molecules (monomers) in a regular pattern.

Polymorphism
a nucleotide difference (variant) in the DNA sequence of a gene. Most polymorphisms are harmless and are part of normal human genetic variation, but some polymorphisms affect the function of the gene product (protein).

Polyp
a benign (non-cancerous) mass of tissue that forms on the inside of a hollow organ, such as the colon.

Polyphenolic compound
a phenolic compound that contains more than one phenolic group.

Polyunsaturated fatty acid
a fatty acid with more than one double bond between carbons.

Postprandial
after eating or after a meal.

Prebiotic
a non-digestible, fermentabl fiber that influences the composition of the intestinal microbiota.

Precursor
a molecule which is an ingredient, reactant, or intermediate in a synthetic pathway for a particular product.

Preeclampsia
a condition characterized by a sharp rise in blood pressure during the third trimester of pregnancy. High blood pressure may be accompanied by edema (swelling) and proteinuria (protein in the urine). In some cases, untreated preeclampsia can progress to eclampsia, a life-threatening situation for the woman and child.

Prevalence
the proportion of a population with a specific disease or condition at a given point in time.

Probiotic
live cultures of microorganisms that, when administered in sufficient amounts, benefits the overall health of the host.

Procarcinogen
a carcinogen precursor that must be modified or metabolized to become an active carcinogen.

Prodrug
a precursor to a drug, i.e., an inactive compound that can be metabolized in the body to produc an active drug.

Prognosis
predicted outcome based on the course of a disease.

Proliferation
the reproduction or multiplication of cells.

Promoter
DNA sequence to which RNA polymerase binds to initiate transcription.

Pro-oxidant
an atom or molecule that promotes oxidation of another atom or molecule by accepting electrons. Examples of pro-oxidants include free radicals, reactive oxygen species (ROS), and reactive nitrogen species (RNS).

Prophylaxis
prevention, often refers to a treatment used to prevent a disease.

Prospective cohort study
an observational study in which a group of people—known as a cohort—are interviewed or tested for risk factors (e.g., nutrient intake), and then followed up at subsequent times to determine their status with respect to a disease or health outcome.

Prostaglandin
cell-signaling molecule that is involved in inflammation. Cyclooxygenases catalyze the formation of prostaglandins from eicosanoids, such as arachidonic acid and eicosapentaenoic acid (EPA).

Prostate
a gland in men, located at the base of the bladder and surrounds the urethra. The prostate produces fluid that forms part of semen. If the prostate becomes enlarged it may exert pressure on the urethra and cause urinary symptoms. Prostate cancer is one of the most common types of cancer in men.

Prostate-specific antigen (PSA)
a compound normally secreted by the prostate that can be measured in the blood. If prostate cancer is developing, the prostate secretes larger amounts of PSA. Blood tests for PSA are used to screen for prostate cancer and to follow up on prostate cancer treatment.

Protein
a complex organic molecule composed of amino acids in a specific order. The order is determined by the sequence of nucleic acids in a gene coding for the protein. Proteins are required for the structure, function, and regulation of the body's cells, tissues, and organs, and each protein has unique functions.

Proteoglycan
a large compound comprised of protein and polysaccharide units known as glycosaminoglycans (GAGs). GAGs are polymers of sugars and amino sugars, such as glucosamine or galactosamine. Proteoglycans are integral components of structural tissues like bone and cartilage.

Proteolysis
the breakdown of proteins by protease enzymes.

Proton
an elementary particle identical to the nucleus of a hydrogen atom, which along with neutrons, is a constituent of all other atomic nuclei. A proton carries a positive charge equal and opposite to that of an electron.

Pruritus
itching.

Psoriasis
a chronic skin condition often resulting in a red, scaly rash located over the surfaces of the elbows, knees, scalp, and around or in the ears, navel, genitals, or buttocks. Approximately 10-15% of patients with psoriasis develop joint inflammation (psoriatic arthritis). Psoriasis is thought to be an autoimmune condition.

Pyruvate kinase deficiency
a hereditary deficiency of the enzyme pyruvate kinase. Pyruvate kinase deficiency results in hemolytic anemia.

Quartile
one-fourth of a sample or population.

Quintile
one-fifth of a sample or population.

Glossary: R

Back to top

Racemic mixture
a mixture of equal amounts of isomers that are mirror images of each other (enantiomers).

Radiation therapy
the local use of radiation to destroy cancer cells or stop them from dividing and growing.

Randomized controlled trial (RCT)
a clinical trial with at least one active treatment group and a control (placebo) group. In RCTs, participants are chosen for the experimental and control groups at random and are not told whether they are receiving the active or placebo treatment until the end of the study. This type of study design can provide evidence of causality.

Randomized design
an experiment in which participants are chosen for the experimental and control groups at random, in order to reduce bias caused by self-selection into experimental and control groups. This type of study design can provide evidence of causality.

RDA
recommended dietary allowance. Established by the Food and Nutrition Board of the US Institute of Medicine, the RDA is the average daily dietary intake level of a nutrient sufficient to meet the requirements of nearly all healthy individuals in a specific life stage and gender group.

Reactive nitrogen species (RNS)
highly reactive chemicals, containing nitrogen, that react easily with other molecules, resulting in potentially damaging modifications.

Reactive oxygen species (ROS)
highly reactive chemicals, containing oxygen, that react easily with other molecules, resulting in potentially damaging modifications.

Recall bias
a type of measurement error caused by inaccuracies in the recollection of study participants regarding past behaviors and experiences.

Receptor
a specialized molecule inside or on the surface of a cell that binds a specific chemical (ligand). Ligand binding usually results in a change in activity within the cell.

Recessive trait
a trait that is expressed only when two copies of the gene responsible for the trait are present.

Rectum
the last portion of the large intestine, connecting the sigmoid colon (above) to the anus (below). The rectum stores stool until it is evacuated from the body.

Redox reaction
another term for an oxidation-reduction reaction. A redox reaction is any reaction in which electrons are removed from one molecule or atom and transferred to another molecule or atom. In such a reaction one substance is oxidized (loses electrons) while the other is reduced (gains electrons).

Reducing equivalent
an amount of a reducing compound that donates the equivalent of one mole of electrons or hydrogen ions in a redox reaction.

Reduction
a chemical reaction in which a molecule or atom gains electrons.

Reepithelialization
a rapid process of cell growth by which the epidermis repairs itself after a wounding event. The goal of reepithelialization is to re-establish a functional barrier that protects underlying cells from environmental exposures.

Relative Risk (RR)
the probability of a negative outcome in the exposed group divided by the probability of the negative outcome in the non-exposed (control) group.

Renal
refers to the kidneys.

Replete
in nutrition, having fulfilled nutrient requirements.

Residual confounding
results when investigators fail to completely control for confounders by adjustment in statistical analyses.

Residue
a single unit within a polymer, such as an amino acid within a protein.

Resorption
the process of breaking down or assimilating something. With respect to bone, resorption refers to the breakdown of bone by osteoclasts, resulting in the release of calcium and phosphate (bone mineral) into the blood.

Response element
a sequence of nucleotides in a gene that can be bound by a protein. Proteins that bind to response elements in genes are sometimes called transcription factors or binding proteins. Binding of a transcription factor to a response element regulates the production of specific proteins by inhibiting or enhancing the transcription of genes that encode those proteins.

Restenosis
with respect to the coronary arteries, restenosis refers to the reocclusion of a coronary artery after it has been dilated using coronary angioplasty.

Retina
the nerve layer that lines the back of the eye. In the retina, images created by light are converted to nerve impulses, which are transmitted to the brain via the optic nerve.

Retrospective study
an epidemiological study that looks back in time. A retrospective study begins after the exposure and the disease have occurred. Most case-control studies are retrospective.

Reverse causation
a concept that refers to the counterintuitive direction in a cause-and-effect association, when it is the effect that influences the cause; E.g., if low vitamin D status is common in people affected by multiple sclerosis (MS), it might be because those with MS spend less time outdoors and therefore synthesize less vitamin D in their skin (reverse causation), rather than because poor vitamin D status increases the risk of MS.

Rheumatoid arthritis
a chronic autoimmune disease characterized by inflammation of the synovial lining of the joints. Rheumatoid arthritis may also affect other organs of the body, including the skin, eyes, lungs, and heart.

Ribonucleotide
a molecule consisting of a five-carbon sugar (ribose), a nitrogen-containing base, and one or more phosphate groups.

Rickets
often the result of vitamin D deficiency. Rickets affects children while their bones are still growing. It is characterized by soft and deformed bones and is the result of an impaired incorporation of calcium and phosphate into the skeleton.

Risk
the probability of a negative outcome occurring.

RNA
ribonucleic acid; a single-stranded nucleic acid composed of many nucleotides. The nucleotides in RNA are composed of a nitrogen-containing base (adenine, guanine, cytosine, or uracil), a five-carbon sugar (ribose) and a phosphate group. RNA functions in the translation of the genetic information encoded in DNA to proteins.

Rumen
the first part of the stomach of a ruminant.

Ruminant
an animal that chews cud. Ruminant animals include cattle, goats, sheep, and deer.

Glossary: S

Back to top

Satiety
a state of fullness.

Saturated fatty acid
a fatty acid with no double bonds between carbon atoms.

Scavenge (free radicals)
to combine readily with free radicals, preventing them from reacting with other molecules.

Schizophrenia
a debilitating brain disorder that affects about 1% of the world's population. Symptoms may include hallucinations, delusions, thought disorders, disorders of movement, cognitive deficits, lack of emotional expression, or impaired ability to speak, plan, and interact with others. Although its cause is not known, schizophrenia is thought to result from a combination of genetic and environmental factors.

Scurvy
a disorder caused by lack of vitamin C. Symptoms include anemia, bleeding gums, tooth loss, joint pain, and fatigue. Scurvy is treated by supplying foods high in vitamin C, as well as with vitamin C supplements.

Sebaceous gland
gland found at the base of hair follicles that secretes sebum.

Sebocyte
a sebum-producing cell in the skin.

Sebum
a waxy/oily substance secreted by mammals that coats the outer layer of the skin.

Seizure
uncontrolled electrical activity in the brain, which may produce a physical convulsion, minor physical signs, thought disturbances, or a combination of symptoms.

Senile plaque
plaques made by deposits of β-amyloid peptides in Alzheimer's disease.

Serotonin
5-hydroxytryptamine. Serotonin is a neurotransmitter that may also function as a vasoconstrictor (substance that causes blood vessels to narrow).

Serum
whole blood without clotting factors. Serum is separated from blood cells using a centrifuge. Unlike plasma, serum lacks clotting factors because it is obtained from blood that has been allowed to clot.

Short bowel syndrome
a malabsorption syndrome resulting from the surgical removal of an extensive portion of the small intestine.

Sickle cell anemia
a hereditary disease in which a mutation in the gene for one of the proteins that comprises hemoglobin results in the formation of defective hemoglobin molecules known as hemoglobin S. Individuals who are homozygous for this mutation (possess two genes for hemoglobin S) have red blood cells that change from the normal discoid shape to a sickle shape when the oxygen supply is low. These sickle-shaped cells are easily trapped in capillaries and damaged, resulting in severe anemia. Individuals who are heterozygous for the mutation (possess one gene for hemoglobin S and one normal hemoglobin gene) have increased resistance to malaria.

Sideroblastic anemia
a group of anemias that are all characterized by the accumulation of iron deposits in the mitochondria of immature red blood cells. These abnormal red blood cells do not mature normally, and many are destroyed in the bone marrow before reaching the circulation. Sideroblastic anemias can be hereditary, idiopathic (unknown cause), or caused by such diverse factors as certain drugs, alcohol, or copper deficiency.

Signal transduction pathway
a cascade of events that allows a signal outside a cell to result in a functional change inside the cell. Signal transduction pathways play important roles in regulating numerous cellular functions in response to changes in a cell's environment.

Sleep apnea
a sleep disorder characterized by repeated cessation of breathing.

Small intestine
the part of the digestive tract that extends from the stomach to the large intestine. The small intestine includes the duodenum (closest to the stomach), the jejunum, and the ileum (closest to the large intestine).

Soluble
capable of being dissolved.

Sorbitol
the polyol (sugar alcohol) corresponding to glucose.

Spermatogenesis
the formation and development of mature spermatozoa.

Spermatozoon
the mature male reproductive cell.

Spina bifida
a birth defect, also known as a neural tube defect, resulting from failure of the lower end of the neural tube to close during embryonic development. Spina bifida, the most common cause of infantile paralysis, is characterized by a lack of protection of the spinal cord by its membranes and vertebral bones.

Spongiosis
intercellular edema in the epidermis.

Sprue
also known as celiac sprue and celiac disease, it is an inherited disease in which the intestinal lining is inflamed in response to the ingestion of a protein known as gluten. Treatment of celiac disease involves the avoidance of gluten, which is present in many grains, including wheat, rye, oats, and barley. Inflammation and atrophy of the lining of the small intestine leads to impaired nutrient absorption.

Statin
a drug that inhibits the enzyme, 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase, thus decreasing endogenous synthesis of cholesterol and lowering blood cholesterol concentrations.

Status
the state of nutrition of an individual with respect to a specific nutrient. Diminished or low status indicates inadequate supply or stores of a specific nutrient for optimal physiological functioning.

Steatosis
the accumulation of fat in the liver.

Stenosis
obstruction or narrowing of a passage. Coronary stenosis refers specifically to obstruction or narrowing of a coronary artery, which supplies blood to the heart muscle (myocardium).

Steroid
a molecule related to cholesterol. Many important hormones, such as estrogen and testosterone, are steroids.

Steroid hormone receptor
a protein within a cell which binds to a specific steroid hormone. Binding of the steroid hormone changes the shape of the receptor protein and activates it, allowing it to activate gene transcription. In this way, a steroid hormone can activate the synthesis of specific proteins.

Stratum corneum
the outer layer of skin; consists of corneocytes that are connected by various proteins and lipids to form a tight barrier around underlying tissue.

Stress fracture
a hairline or microscopic break in a bone, usually due to repetitive stress rather than trauma. Stress fractures are usually painful, and may be undetectable by X-ray. Although they may occur in almost any bone, common sites of stress fractures are the tibia (lower leg) and metatarsals (foot).

Stroke
damage that occurs to a part of the brain when its blood supply is suddenly interrupted (ischemic stroke) or when a blood vessel ruptures and bleeds into the brain (hemorrhagic stroke). A stroke is also called a cerebrovascular accident (CVA).

Subclinical
without clinical signs or symptoms; sometimes used to describe the early stage of a disease or condition, before symptoms are detectable by clinical examination or laboratory tests.

Subcutaneous
under the skin.

Substrate
a reactant in an enzyme-catalyzed reaction.

Sucrose
a disaccharide composed of two monosaccharides: glucose and fructose. Also known as cane sugar or table sugar.

Supplement
a nutrient or phytochemical supplied in addition to that which is obtained in the diet.

Synapse
cell-cell junction that allows chemical or electrical signals to be passed from a neuron to another neuron or muscle cell.

Synaptic plasticity
the ability of neurons to change the number or strength of their synaptic connections. Synaptic plasticity is believed to underlie the processes of learning and memory.

Syndrome
a combination of symptoms that occur together and is indicative of a specific condition or disease.

Synergistic
when the effect of two treatments together is greater than the sum of the effects of the two individual treatments, the effect is said to be synergistic.

Synthesis
the formation of a chemical compound from its elements or precursor compounds.

Systematic review
a structured review of the literature designed to answer a clearly formulated question. Systematic reviews use systematic and explicitly predetermined methods to identify, select and critically evaluate research relevant to the question, and to collect and analyze data from the studies that are included in the review. Statistical methods, such as meta-analysis, may be used to summarize the results of the included studies.

Systemic lupus erythematosus (SLE)
a chronic autoimmune disease characterized by inflammation of the connective tissue. SLE is more common in women than men and may result in inflammation and damage to the skin, joints, blood vessels, lungs, heart, and kidneys.

Systolic blood pressure
the highest arterial pressure measured during the heart beat cycle, and the first number in a blood pressure reading (e.g., 120/80).

Glossary: T

Back to top

Tannins
any of a large group of plant-derived compounds. Tannins tend to be bitter tasting and may function in pigment formation and plant protection.

Telangiectasias
broken capillaries in the skin.

Telomere
the segment of DNA at each end of a chromosome.

Teratogen
an agent that interferes with normal development of an embryo or fetus.

Tertile
one-third of a sample or population.

Tetany
a condition of prolonged and painful spasms of the voluntary muscles, especially the fingers and toes (carpopedal spasm), as well as the facial musculature.

Thalassemia major
Beta thalassemia is a genetic disorder that results in abnormalities of the globin (protein) portion of hemoglobin. An individual who is homozygous for the β thalassemia gene (has two copies of the β thalassemia gene) is said to have thalassemia major. Infants born with thalassemia major develop severe anemia a few months after birth, accompanied by pallor, fatigue, poor growth, and frequent infections. Blood transfusions are used to treat thalassemia major but cannot cure it.

Thalassemia minor
Individuals who are heterozygous for the β thalassemia gene (carry one copy of the β thalassemia gene) are said to have thalassemia minor or thalassemia trait. These individuals are

generally healthy but can pass the β thalassemia gene to their children and are said to be carriers of the β thalassemia gene.

Thermoregulation
the process of controlling body temperature to prevent both excessive cooling and warming.

Threshold
the point at which a physiological effect begins to be produced, for example, the degree of stimulation of a nerve which produces a response or the level of a chemical in the diet that results in a disease.

Thyroid
a butterfly-shaped gland in the neck that secretes thyroid hormones. Thyroid hormones regulate a number of physiologic processes, including growth, development, metabolism, and reproductive function.

Thyroid follicular cancer
a cancer of the thyroid gland that constitutes about 30% of all thyroid cancers. It has a greater rate of recurrence and metastases (spreading to other organs) than thyroid papillary cancer.

Thyroid papillary cancer
the most common form of thyroid cancer, which most often affects women of childbearing age. Thyroid papillary cancer has a lower rate of recurrence and metastases (spreading to other organs) than thyroid follicular cancer.

Topical
applied to the skin or other body surface.

Total Parenteral Nutrition (TPN)
intravenous (I.V.) feeding that provides patients with essential nutrients when they are too ill to eat normally.

Trabecular bone
also known as spongy or cancellous bone, the type of bone found within the ends of long bones and inside flat bones and spinal vertebrae.

Transcription
(DNA transcription); the process by which one strand of DNA is copied into a complementary sequence of RNA.

Transcription factor
a protein that functions to initiate, enhance, or inhibit the transcription of a gene. Transcription factors can regulate the formation of a specific protein encoded by a gene.

***Trans* fat**
hydrogenated or partially hydrogenated oils.

Transient ischemic attack (TIA)
sometimes called a small or mini stroke. TIAs are caused by a temporary disturbance of blood supply to an area of the brain, resulting in a sudden, brief (usually less than one hour) disruptions in certain brain functions.

Translation
(RNA translation); the process by which the sequence of nucleotides in a messenger RNA (mRNA) molecule directs the incorporation of amino acids into a protein.

Trauma
an injury or wound.

Tremor
trembling or shaking of a part or all of the body.

Triglyceride
lipid consisting of three fatty acid molecules bound to a glycerol backbone. Triglycerides are the principal form of fat in the diet, although they are also synthesized endogenously. Triglycerides are stored in adipose tissue and represent the principal storage form of fat. Elevated serum triglycerides are a risk factor for cardiovascular disease.

Trimethylaminuria
a hereditary disorder characterized by increased urinary excretion of trimethylamine, a compound with a "fishy" or foul odor.

T-score
a clinical measure of bone mineral density (BMD) obtained by dual X-ray absorptiometry (DEXA).

Tuberculosis
an infection caused by bacteria called *mycobacterium tuberculosis*. Many people infected with tuberculosis have no symptoms because it is dormant. Once active, tuberculosis may cause damage to the lungs and other organs. Active tuberculosis is also contagious and is spread through inhalation. Treatment of tuberculosis involves taking antibiotics and vitamins for at least six months.

Typhoid
an infectious disease spread by the contamination of food or water supplies with the bacteria called salmonella typhi. Food and water can be contaminated directly by sewage or indirectly by flies or poor hygiene. Though rare in the US, it is common in some parts of the world. Symptoms include fever, abdominal pain, diarrhea, and a rash. It is treated with antibiotics and intravenous fluids. Vaccination is recommended to those traveling to areas where typhoid is common.

Glossary: U

Back to top

UL
tolerable upper intake level. Established by the Food and Nutrition Board of the US Institute of Medicine, the UL is the highest level of daily intake of a specific nutrient likely to pose no risk of adverse health effects in almost all individuals of a specified age.

Ulcerative colitis
a chronic inflammatory disease of the colon and rectum. Symptoms of ulcerative colitis include abdominal pain, cramping, and bloody diarrhea.

Ultrasonography
a test in which high-frequency sound waves (ultrasound) are bounced off tissues and the echoes are converted into a picture (sonogram).

Unsaturated fatty acid
a fatty acid with at least one double bond between carbons.

Uremia
an excessive concentration of urea and other nitrogenous waste products in the blood that are normally excreted by the kidneys.

Uric acid
an antioxidant produced by the body.

Glossary: V

Back to top

Vascular dementia
dementia resulting from cerebrovascular disease, for example, a cerebrovascular accident (stroke).

Vascular endothelium
the single cell layer that lines the inner surface of blood vessels. Healthy endothelial function promotes vasodilation and inhibits platelet aggregation (clot formation).

Vascularization
the creation of new blood vessels or the extension of existing blood vessels into tissue.

Vasoconstriction
narrowing of a blood vessel.

Vasodilation
relaxation or opening of a blood vessel.

Vehicle
the material in which a treatment compound is dissolved.

Ventricles
the two lower chambers of the heart that pump blood to the body (left) and the lungs (right).

Vertebral
of or pertaining to a vertebra, 1 of the 23 bones that comprise the spine.

Vesicle
literally a small bag or pouch. Inside a cell, a vesicle is a small organelle surrounded by its own membrane.

Virulent
marked by a rapid, severe, or damaging course.

Virus
a microorganism, which cannot grow or reproduce apart from a living cell. Viruses invade living cells and use the synthetic processes of infected cells to survive and replicate.

Vitamin
an organic (carbon-containing) compound necessary for normal physiological function that cannot be synthesized in adequate amounts and must therefore be obtained in the diet.

VLDL
Very-low-density lipoprotein cholesterol. VLDLs transport lipids in the bloodstream.

Glossary: W, X, Y, Z

Back to top

Xenobiotic
a chemical compound that is foreign to the organism. Xenobiotics may include dietary factors, toxins, pharmaceuticals, and pollutants.

Xenobiotic metabolism
a series of enzymatic reactions that convert a foreign chemical compound into an inert substance that can be safely excreted from the body. The three phases of xenobiotic metabolism include: (i) activation, (ii) functionalization, and (iii) efflux.

Xenograft
a transplant of tissue from a donor of one species to a recipient of another species.

Zollinger-Ellison syndrome
a rare disorder caused by a tumor called a gastrinoma, most often occurring in the pancreas. The tumor secretes the hormone gastrin, which causes increased production of gastric acid leading to severe recurrent ulcers of the esophagus, stomach, and the upper portions of the small intestine.

Nutrient Index

Articles on the following nutrients, phytochemicals, food, and beverages are available in the Linus Pauling Institute's Micronutrient Information Center:

Disease Index

- **Alzheimer's Disease**
  - L-Carnitine | Choline | Copper | Curcumin | Essential Fatty Acids | Folate | Fruit and Vegetables | Iron | Moderate Alcohol Consumption | Thiamin | Vitamin B$_6$ | Vitamin B$_{12}$ | Vitamin C | Vitamin D | Vitamin E | Zinc
- **Angina Pectoris**
  - L-Carnitine | Coenzyme Q$_{10}$
- **Asthma**
  - Magnesium | Omega-3 Fatty Acids | Vitamin C
- **Atherosclerosis**
  - Carotenoids | Coenzyme Q$_{10}$ | Copper | Essential Fatty Acids | Flavonoids | Garlic | Iron | Magnesium | Moderate Alcohol Consumption | Resveratrol | Soy Isoflavones | Vitamin C | Vitamin E
- **Athletic Performance**
  - L-Carnitine | Coenzyme Q$_{10}$
- **Autoimmune Disease**
  - Omega-3 Fatty Acids | Vitamin D
- **Bone Health (see the articles: Bone Health In Brief, Bone Health In Depth, and Osteoporosis)**
- **Cancer**
  - **General**
    - L-Carnitine | Carotenoids | Coenzyme Q$_{10}$ | Coffee | Cruciferous Vegetables | Curcumin | Glycemic Index and Glycemic Load | Flavonoids | Fruit and Vegetables | Heavy Alcohol Consumption | Indole-3-Carbinol | Iron | Isothiocyanates | Niacin | Phytosterols | Resveratrol | Riboflavin | Vitamin B$_6$ | Selenium | Tea | Thiamin | Vitamin B$_6$ | Vitamin B$_{12}$ | Vitamin C | Vitamin D | Vitamin E | Whole Grains
  - **Breast Cancer**
    - Alcohol Consumption | Carotenoids | Coenzyme Q$_{10}$ | Coffee | Cruciferous Vegetables | Curcumin | Fiber | Flavonoids | Folate | Fruit and Vegetables | Glycemic Index and Glycemic Load | Iron | Legumes | Lignans | Molybdenum | Riboflavin | Soy Isoflavones | Tea | Vitamin B$_6$ | Vitamin B$_{12}$ | Vitamin C | Vitamin D
  - **Colorectal Cancer**
    - Calcium | Carotenoids | Coffee | Cruciferous Vegetables | Curcumin | Fiber | Folate | Fruit and Vegetables | Garlic | Heavy Alcohol Consumption | Iron | Legumes | Vitamin C | Vitamin D | Whole Grains
  - **Esophageal Cancer**
    - Coffee | Fruit and Vegetables | Heavy Alcohol Consumption | Iron | Molybdenum | Tea | Whole Grains
  - **Gynecologic Cancers**
    - Legumes | Lignans | Soy Isoflavones | Tea
  - **Liver Cancer**
    - Chlorophyllin | Choline | Coffee | Fruit and Vegetables | Heavy Alcohol Consumption | Iron
  - **Lung Cancer**
    - Carotenoids | Coffee | Cruciferous Vegetables | Fruit and Vegetables | Vitamin A | Vitamin D
  - **Prostate Cancer**
    - Calcium | Carotenoids | Coffee | Cruciferous Vegetables | Curcumin | Flavonoids | Legumes | Lignans | Soy Isoflavones | Vitamin D
  - **Gastric Cancer**
    - Coffee | Cruciferous Vegetables | Fruit and Vegetables | Garlic | Sodium | Tea | Vitamin C
- **Cardiac Arrhythmias**
  - Coffee | Heavy Alcohol Consumption | Omega-3 Fatty Acids | Potassium

Cardiovascular Disease

- **General**
  - Calcium | L-Carnitine | Carotenoids | Choline | Chromium | Coenzyme Q$_{10}$ | Copper | Cruciferous Vegetables | Fiber | Flavonoids | Folate | Fruit and Vegetables | Garlic | Glycemic Index and Glycemic Load | Heavy Alcohol Consumption | Iron | Legumes | Lignans | Magnesium | Moderate Alcohol Consumption | Niacin | Nuts | Omega-3 Fatty Acids | Omega-6 Fatty Acids | Phytosterols | Resveratrol | Selenium | Soy Isoflavones | Tea | Thiamin | Vitamin B$_6$ | Vitamin B$_{12}$ | Vitamin C | Vitamin E | Vitamin K | Whole Grains
- **Angina Pectoris**
  - L-Carnitine | Coenzyme Q$_{10}$
- **Atherosclerosis**
  - Carotenoids | Coenzyme Q$_{10}$ | Copper | Essential Fatty Acids | Flavonoids | Garlic | Iron | Magnesium | Moderate Alcohol Consumption | Resveratrol | Soy Isoflavones | Vitamin C | Vitamin E
- **Cardiac Arrhythmias**
  - Coffee | Heavy Alcohol Consumption | Omega-3 Fatty Acids | Potassium
- **Congestive Heart Failure**
  - L-Carnitine | Coenzyme Q$_{10}$ | Moderate Alcohol Consumption | Sodium | Thiamin | Vitamin C | Vitamin D
- **Coronary Heart Disease**
  - Carotenoids | Coffee | Fiber | Fruit and Vegetables | Glycemic Index and Glycemic Load | Iron | Legumes | Magnesium | Moderate Alcohol Consumption | Nuts | Omega-3 Fatty Acids | Omega-6 Fatty Acids | Phytosterols | Resveratrol | Tea | Vitamin C | Whole Grains
- **High Blood Pressure**
  - Calcium | Coenzyme Q$_{10}$ | Coffee | Fiber | Flavonoids | Garlic | Glycemic Index and Glycemic Load | Heavy Alcohol Consumption | Magnesium | Potassium | Riboflavin | Sodium | Tea | Vitamin C | Vitamin D | Whole Grains
- **High Homocysteine**
  - Choline | Coffee | Folate | Legumes | Riboflavin | Vitamin B$_6$ | Vitamin B$_{12}$
- **High Total and LDL Cholesterol**
  - Coffee | Essential Fatty Acids | Fiber | Flavonoids | Garlic | Glycemic Index and Glycemic Load | Niacin | Nuts | Pantothenic Acid | Phytosterols | Soy Isoflavones | Tea | Vitamin C | Whole Grains
- **High Triglycerides**
  - Glycemic Index and Glycemic Load | Niacin | Omega-3 Fatty Acids | Tea | Vitamin C
- **Intermittent Claudication in Peripheral Arterial Disease**
  - L-Carnitine | Moderate Alcohol Consumption
- **Low HDL Cholesterol**
  - Flavonoids | Moderate Alcohol Consumption | Niacin | Regular Physical Activity | Tea
- **Myocardial Infarction**
  - L-Carnitine | Coenzyme Q$_{10}$ | Copper | Fiber | Fruit and Vegetables | Iron | Magnesium | Moderate Alcohol Consumption | Niacin | Nuts | Omega-3 Fatty Acids | Selenium | Tea | Vitamin C | Vitamin E
- **Stroke**
  - Carotenoids | Choline | Coffee | Folate | Glycemic Index and Glycemic Load | Heavy Alcohol Consumption | Magnesium | Moderate Alcohol Consumption | Nuts | Potassium | Tea | Vitamin C | Vitamin E | Whole Grains
- **Carpal Tunnel Syndrome**
  - Vitamin B$_6$
- **Cataracts**
  - Carotenoids | Fruit and Vegetables | Riboflavin | Thiamin | Vitamin C | Vitamin E
- **Celiac Disease**
  - Copper | Iron | Magnesium | Vitamin B$_{12}$ | Zinc
- **Chronic Obstructive Pulmonary Disease (COPD)**
  - Fruit and Vegetables | Isothiocyanates
- **Cirrhosis**
  - Choline | Coffee | Heavy Alcohol Consumption | Iron
- **Cognitive Function (see the articles: Cognitive Function In Brief and Cognitive Function In Depth)**
- **Common Cold (see MIC article)**
  - Vitamin C | Zinc
- **Congestive Heart Failure**
  - L-Carnitine | Coenzyme Q$_{10}$ | Moderate Alcohol Consumption | Sodium | Thiamin | Vitamin C | Vitamin D
- **Coronary Heart Disease**
  - Carotenoids | Coffee | Fiber | Fruit and Vegetables | Glycemic Index and Glycemic Load | Iron | Legumes | Magnesium | Moderate Alcohol Consumption | Nuts | Omega-3 Fatty Acids | Omega-6 Fatty Acids | Phytosterols | Resveratrol | Tea | Vitamin C | Whole Grains
- **Depression**
  - L-Carnitine | Curcumin | Omega-3 Fatty Acids | Vitamin B$_6$ | Vitamin B$_{12}$ | Zinc
- **Diabetes Mellitus**
  - **Gestational Diabetes**
    - Chromium | Omega-3 Fatty Acids | Vitamin D
  - **Type 1 Diabetes**
    - Coenzyme Q$_{10}$ | Niacin | Vitamin D
  - **Type 2 Diabetes**
    - Biotin | L-Carnitine | Chromium | Coenzyme Q$_{10}$ | Coffee | Curcumin | Glycemic Index and Glycemic Load | Fiber | Flavonoids | Fruit and Vegetables | Iron | Legumes | Lipoic Acid | Magnesium | Manganese | Moderate Alcohol Consumption | Nuts | Omega-3 Fatty Acids | Resveratrol | Tea | Vitamin C | Vitamin D | Vitamin E | Whole Grains | Zinc
- **Epilepsy**
  - Manganese
- **Fatty Liver Disease**
  - Choline | Essential Fatty Acids | Vitamin E
- **Friedreich's Ataxia**
  - Coenzyme Q$_{10}$ | Niacin
- **Glaucoma**
  - Choline
- **Growth and Development**
  - Iron | Omega-3 Fatty Acids | Zinc
- **High Blood Pressure**
  - Calcium | Coenzyme Q$_{10}$ | Coffee | Fiber | Flavonoids | Garlic | Glycemic Index and Glycemic Load | Heavy Alcohol Consumption | Magnesium | Potassium | Riboflavin | Sodium | Tea | Vitamin C | Vitamin D | Whole Grains
- **High Homocysteine**
  - Choline | Coffee | Folate | Legumes | Riboflavin | Vitamin B$_6$ | Vitamin B$_{12}$
- **High Total and LDL Cholesterol**
  - Coffee | Essential Fatty Acids | Fiber | Flavonoids | Garlic | Glycemic Index and Glycemic Load | Niacin | Nuts | Pantothenic Acid | Phytosterols | Soy Isoflavones | Tea | Whole Grains
- **High Triglycerides**
  - Glycemic Index and Glycemic Load | Niacin | Omega-3 Fatty Acids | Tea
- **HIV/AIDS**
  - L-Carnitine | Niacin | Selenium | Vitamin A | Zinc
- **Huntington's Disease**
  - Coenzyme Q$_{10}$ | Thiamin
- **Immune Function (see the articles: Immunity In Brief and Immunity In Depth)**
  - Copper | Iron | Pantothenic Acid | Selenium | Vitamin A | Vitamin B$_6$ | Vitamin C | Vitamin D | Vitamin E | Zinc
- **Inflammation (see MIC article)**
- **Inflammatory Bowel Disease**
  - Omega-3 Fatty Acids | Vitamin D
- **Intermittent Claudication in Peripheral Arterial Disease**
  - L-Carnitine | Moderate Alcohol Consumption
- **Kidney Failure/Dialysis**
  - L-Carnitine | Omega-3 Fatty Acids (IgA Nephropathy) | Phosphorus
- **Kidney Stones**
  - Calcium | Potassium | Sodium | Tea | Vitamin B$_6$ | Vitamin C
- **Lead Poisoning**
  - Calcium | Iron | Vitamin C
- **Low HDL Cholesterol**
  - Flavonoids | Moderate Alcohol Consumption | Niacin | Regular Physical Activity | Tea
- **Macular Degeneration**
  - Carotenoids | Fruit and Vegetables | Vitamin E | Zinc
- **Metabolic Syndrome (see MIC)**
  - Chromium | Essential Fatty Acids | Fiber | Iron | Magnesium
- **Migraine Headache**
  - Magnesium | Riboflavin
- **Multiple Sclerosis (MS)**
  - Biotin | Lipoic Acid | Riboflavin | Vitamin D
- **Myocardial Infarction**
  - L-Carnitine | Coenzyme Q$_{10}$ | Copper | Fiber | Fruit and Vegetables | Iron | Magnesium | Moderate Alcohol Consumption | Niacin | Nuts | Omega-3 Fatty Acids | Selenium | Tea | Vitamin C | Vitamin E
- **Neurodegenerative Diseases**
  - **General**
    - Coenzyme Q$_{10}$ | Coffee | Essential Fatty Acids | Flavonoids | Folate | Iron | Soy Isoflavones | Thiamin | Vitamin B$_6$ | Vitamin B$_{12}$ | Vitamin D | Vitamin E
  - **Alzheimer's Disease**
    - L-Carnitine | Choline | Copper | Curcumin | Essential Fatty Acids | Folate | Fruit and Vegetables | Iron | Moderate Alcohol Consumption | Thiamin | Vitamin B$_6$ | Vitamin B$_{12}$ | Vitamin C | Vitamin D | Vitamin E | Zinc

Your Support Allows Us to Keep the Micronutrient Information Center Freely Available

Your gift will help us maintain and improve the Micronutrient Information Center; 95% of your donation will go directly to fund article updates by our Ph.D. nutrition scientists. Contributions are made through the Oregon State University Foundation, the Institute's parent charity. All gifts are treated as restricted gifts to the Linus Pauling Institute's Micronutrient Information Center and are tax deductible under IRS regulations. *More information about the Institute's fundraising policies and relationships with Oregon State University*

Give online:

Donate to the Micronutrient Information Center online

By mail:

To send a check, please make your check payable to the "OSU Foundation" and mail to: Andrew Norwood, OSU Foundation: 4238 SW Research Way, Corvallis, Oregon 97333. Please mark "Linus Pauling Institute's MIC" in the notation section of your check. You will receive a formal gift receipt for your records.

By phone:

You can make your gift to the Linus Pauling Institute's Micronutrient Information Center via credit card by calling the OSU Foundation at 800-354-7281 or 541-737-4218.

Donating securities:

Giving securities often has advantages for donors over gifts of cash. You can receive charitable deduction for today's market value of the securities, and you are not liable for capital gains, since the assets are donated instead of sold. To find out more about donating stock to the Linus Pauling Institute, you or your financial advisor can call the OSU Foundation (800-354-7281).

Planned gift options:

Including the Linus Pauling Institute in your Will or Trust:

You can easily make the Institute part of your estate plans by including special language in your will or trust. Please let us know of your intentions so that we can better steward your gift according to your wishes.

Gifts that provide donors income:

There are several planned gifts, such as charitable remainder trusts and gift annuities, which can provide donors with tax benefits and a lifetime income stream, even as you prepare a future gift to support the Institute. For more information, please contact Andrew Norwood, OSU Foundation, LPI Director of Development. Further reading material is on the OSU Foundation website.

Dedicating your gift:

If you wish to dedicate your gift in honor or in memory of a friend or loved one, please include a note with your contribution indicating the honoree and the name and address of those you would like us to notify (please print). A letter is sent to the honoree or their family indicating that the gift has been made (the amount is not included).

Contact:

Drug-Nutrient Interactions

Although drug-nutrient interactions have not been systematically studied, there are a number of known interactions reported in the scientific literature. The interactions listed in **Table 1** are not meant to be comprehensive but include some of the more common clinically relevant drug-nutrient interactions, especially in the context of micronutrient inadequacy. For additional references on drug-nutrient interactions, see Table 2.

It is important to note that specific criteria to label interactions as "clinically significant" have not been established, although a threshold of ≥20% change in the kinetic and/or dynamic parameter of the drug or nutrient has been proposed (1). Long-term use of the drug is often needed to reach such a threshold and for clinical symptoms of the drug-nutrient interaction to manifest (1).

Table 1. Select Interactions between Drugs and Nutrients

Drug	Micronutrient	Mechanism(s) of Action	Potential Action(s) to Minimize Risk	Reference
Alcohol	Folate	Chronic alcohol abuse has been associated with folate deficiency due to low dietary intake, decreased intestinal absorption, impaired hepatic uptake, and increased excretion of the vitamin.	Ensure adequate intake of folate through diet and/or a daily multivitamin.	(2)
	Riboflavin	Chronic alcohol abuse has been associated with riboflavin deficiency, presumably due to low dietary intake.	Ensure adequate intake of riboflavin through diet and/or a daily multivitamin.	(3)
	Thiamin	Chronic alcohol abuse is associated with thiamin deficiency due to low dietary thiamin intake, impaired absorption and utilization of thiamin, and increased excretion of thiamin.	Thiamin supplementation in alcoholics may prevent Wernicke-Korsakoff's syndrome.	(4)
	Vitamin A	Chronic alcohol abuse depletes the liver of retinol and increases retinol mobilization to extra-hepatic tissues, although the mechanisms are not understood.	Avoid high doses of vitamin A and β-carotene in alcoholics because chronic alcohol abuse increases the risk of retinol-induced hepatotoxicity.	(5, 6)
	Vitamin B$_6$	Low vitamin B$_6$ status in alcoholics may result from inadequate intake and potentially from altered metabolism, although the mechanisms are not fully understood.		(7, 8)
Alendronate (Binosto; Fosamax): see Bisphosphonates				
Amiloride: see Potassium-sparing diuretics				
Antacids	Folate	Use of antacids may slightly impair absorption of synthetic folic acid from supplements due to gastrointestinal pH changes.	Separate folic acid supplementation and drug use by 3 hours.	(9)
	Fluoride	Use of aluminum-containing antacids can decrease fluoride absorption.	Separate antacid intake and fluoride supplements by at least 2 hours.	(10)
	Iron	Use of antacids increases the pH of gastrointestinal contents, which may lead to reduced iron solubility and decreased intestinal absorption of iron.	Separate antacid intake and iron supplements by at least 2 hours.	(11-13)
	Magnesium	Use of magnesium-containing antacids can result in hypermagnesemia in those with impaired renal function since the mineral is not properly excreted.	This might only occur with long-term antacid use; prudent to monitor magnesium intake and magnesium status in patients with renal insufficiency.	(14)
	Manganese	Use of magnesium-containing antacids may decrease absorption of manganese from food or supplements.	Separate antacids and manganese intake by at least 2 hours.	(15)
	Phosphate	Use of aluminum-containing antacids may decrease phosphate absorption and cause hypophosphatemia at high doses.	Hypophosphatemia is usually only a concern with excessive antacid use and very low dietary intake of phosphorus.	(16)
Antibiotics: see Chloramphenicol; Cycloserine; Ethambutol (Myambutol); Isoniazid; Rifampin/Rifampicin (Rifadin); Tetracycline-class antibiotics; Trimethoprim (Primsol); and Quinolone-class antibiotics				
Aspirin	Vitamin C	High doses of aspirin may increase urinary excretion of vitamin C; aspirin might also impair vitamin C absorption in the small intestine. Vitamin C may protect against aspirin-induced damage of the gastric mucosa, possibly through inhibition of iNOS expression.	Long-term use of aspirin might impair vitamin C status. Ensure adequate vitamin C intake from diet and/or supplements.	(17, 18)
	Vitamin E	High doses of supplemental vitamin E may potentiate the antiplatelet effects of aspirin.	Avoid high-dose vitamin E supplements in those taking aspirin.	(19)
Bisphosphonates (alendronate [Binosto, Fosamax], etidronate, ibandronate [Boniva], pamidronate, risedronate [Actonel, Atelvia], zoledronic acid [Reclast])	Calcium	Concomitant intake may decrease bisphosphonate absorption due to complex formation with multivalent cations.	Separate drug and nutrient intake by 2 hours.	(20)
	Iron	Concomitant intake may decrease bisphosphonate absorption due to complex formation with multivalent cations.	Separate drug and nutrient intake by 2 hours.	(15, 20)
	Magnesium	Concomitant intake may decrease bisphosphonate absorption due to complex formation with multivalent cations.	Separate drug and nutrient intake by 2 hours.	(15, 20)
	Zinc	Concomitant intake may decrease bisphosphonate and zinc absorption due to complex formation with multivalent cations.	Separate drug and nutrient intake by 2 hours.	(15)
Bumetanide (Bumex): see Loop diuretics				
Calcitriol (Rocaltrol) and some vitamin D analogs	Phosphate	High doses of calcitriol and some vitamin D analogs may increase intestinal calcium/phosphate absorption and cause hypercalcemia/hyperphosphatemia.	Be aware of a possible interaction in patients with chronic kidney disease.	(21)
Carbamazepine (Carbatrol, Epitol, Equetro, Tegretol, Tegretol-XR)	Biotin	Carbamazepine may competitively inhibit intestinal absorption of biotin, inhibit renal reabsorption of biotin, as well as accelerate biotin catabolism.	Biotin status might be impaired with long-term carbamazepine therapy, although the clinical significance of marginal biotin deficiency is unclear.	(22, 23)
	Grapefruit (flavonoids)	The flavonoids in grapefruit inhibit CYP3A4, increasing the bioavailability and risk of toxicity from carbamazepine.		(24)
	Psyllium	When taken at the same time, psyllium may reduce the intestinal absorption of carbamazepine.	Separate taking carbamazepine and psyllium supplements by at least 2 hours.	(15, 25)
Chloramphenicol	Folate	Chloramphenicol has been documented to induce aplastic anemia in rare cases. Chloramphenicol use might reduce the efficacy of supplemental folic acid by interfering with the hematopoietic response.	Monitor hematological parameters in patients taking chloramphenicol.	(12, 26, 27)
	Vitamin B$_{12}$	Chloramphenicol has been documented	Monitor vitamin B$_{12}$ status in patients taking	(12, 26, 28, 29)

		to induce aplastic anemia in rare cases. Chloramphenicol can cause bone marrow suppression. The drug may decrease intestinal absorption of food-bound, but not supplemental, vitamin B_{12} and possibly interfere with the efficacy of supplemental vitamin B_{12} to treat anemia.	chloramphenicol. Multivitamin or single-nutrient vitamin B_{12} supplementation would be needed with long-term drug treatment.	
	Iron	Chloramphenicol has been documented to induce aplastic anemia in rare cases. Chloramphenicol can cause bone marrow suppression; the efficacy of supplemental iron to treat anemia may be affected by chloramphenicol use.	Monitor iron status in patients taking chloramphenicol. Use the lowest effective dose (<25-30 mg/kg) or select a different antibiotic.	(26, 28, 29)
Chlorothiazide (Diuril, Sodium Diuril): see Thiazide diuretics				
Chlorpromazine (Thorazine)	Riboflavin	Chlorpromazine has been shown to inhibit the incorporation of riboflavin into FAD and FMN, as well as increase urinary excretion of riboflavin in the context on inadequate dietary intake of riboflavin.	Available data come from rodent models as human data are lacking. Assess riboflavin status, and if needed, consider a riboflavin-containing supplement. Separate drug from riboflavin supplements by at least 4 hours to minimize interaction.	(12, 30, 31)
Chlortetracycline: see Tetracycline-class antibiotics				
Chlorthalidone (Hygroton, Thalitone): see Thiazide diuretics				
Cholestyramine (Prevalite, Questran, Questran Light)	Folate	Cholestyramine can bind to folate polyglutamates and decrease absorption of folate from food, thus increasing the risk of folate deficiency.	Folic acid supplementation may help prevent deficiency in patients on long-term cholestyramine therapy. Advise taking folic acid supplements 1 hour before or 4-6 hours following drug intake.	(12, 32)
	Vitamin A	Through interfering with fat absorption, cholestyramine might decrease the absorption of vitamin A.	Separate drug and vitamin supplementation by at least 4 hours.	(15, 32)
	Vitamin B_{12}	Cholestyramine might decrease intestinal absorption of vitamin B_{12}, perhaps by binding to intrinsic factor, which is needed for ileal vitamin absorption.	The extent of such an interaction is not clear, as a study in children found that long-term administration of cholestyramine did not alter serum cobalamin. Monitor vitamin B_{12} status; measuring methylmalonic acid is the specific indicator of vitamin B_{12} deficiency.	(32, 33)
	Vitamin D	Through interfering with bile acids and fat absorption, cholestyramine might decrease the absorption of vitamin D.	Separate drug and vitamin D supplementation by at least 4 hours.	(34)
	Vitamin E	Cholestyramine may theoretically decrease the absorption of fat-soluble vitamins, including vitamin E, through interfering with fat absorption.	Separate drug and vitamin E supplementation by at least 4 hours.	(32)
	Vitamin K	There have been a few case reports of bleeding in those taking cholestyramine. Through interfering with bile acids and fat absorption, cholestyramine might decrease the absorption of vitamin K.	Long-term administration of cholestyramine to children did not affect prothrombin time. To avoid a potential interaction, separate drug and vitamin supplementation by at least 4 hours.	(32, 35, 36)
	Minerals	Cholestyramine might impair intestinal absorption of various minerals (e.g., iron, magnesium, zinc); increased urinary excretion of calcium and magnesium has also been documented.	Human data on the effect of cholestyramine on mineral balance are lacking. Multivitamin/mineral supplementation may help ensure adequacy; separating drug and nutrient supplementation by at least 4 hours would prevent any interaction.	(37, 38)
	Carotenoids	Cholestyramine may inhibit intestinal absorption of carotenoids.	Separate drug and nutrient supplementation by at least 4 hours.	(15)
	Psyllium	Psyllium might enhance the lowering of cholesterol by cholestyramine.		(15)
Cimetidine (Cimetidine Acid Reducer [OTC], Tagamet, Tagamet HB): see Histamine-2 receptor antagonists				
Colchicine (Colcrys, Gloperba, Mitigare)	Vitamin B_{12}	Colchicine may decrease the absorption of vitamin B_{12} from food by disrupting normal function of the ileal mucosa.	Prudent to monitor vitamin B_{12} status in patients taking colchicine; methylmalonic acid buildup is the specific indicator of vitamin B_{12} deficiency.	(39, 40)
Colestipol (Colestid, Colestid Flavored)	Folate	Colestipol may bind to folate polyglutamates and might decease absorption of folate from food, increasing the risk of folate deficiency.	Studies are limited. Folic acid supplementation may help prevent deficiency in patients on long-term colestipol therapy. Advise taking folic acid supplements 1 hour before or 4-6 hours following drug intake.	(41-43)
	Fat-soluble vitamins (vitamins A, D, E, K) and carotenoids	As a bile acid sequestrant, colestipol may interfere with the absorption of fat-soluble vitamins and carotenoids.	Studies are limited and have not shown major effects. Monitor patients on long-term colestipol therapy.	(41, 42, 44)
	Iron	Colestipol and iron may form a chelation complex, decreasing intestinal absorption of iron.	Human data are lacking. Separate drug and iron supplements by at least 4 hours.	(45)
Cycloserine	Vitamin B_6	Cycloserine forms an inactive covalently bound complex with pyridoxal 5'-phosphate and may cause a functional vitamin B_6 deficiency, possibly leading to anemia and peripheral neuropathy.	Vitamin B_6 supplementation (≤50 mg/day) might help prevent deficiency.	(12, 46, 47)
Demeclocycline: see Tetracycline-class antibiotics				
Dexlansoprazole (Dexilant): see Proton-pump inhibitors				
Digoxin (Digitek, Digox, Lanoxin, Lanoxin Pediatric)	Calcium	High doses of supplemental calcium could increase the occurrence of abnormal heart rhythms in those taking digoxin due to calcium elevations in plasma and cardiomyocytes, influencing heart contractility and frequency.	Consider advising patients to maintain a stable intake of calcium and avoid daily fluctuations in intake. Monitor serum concentrations of calcium in patients taking digoxin.	(12, 48)
	Magnesium	Digoxin causes reductions in intracellular magnesium concentrations, as well as increased urinary excretion of the mineral. Magnesium-containing antacids or magnesium supplements may decrease digoxin absorption, which may decrease drug efficacy. Hypomagnesemia may increase the risk for digoxin toxicity through a number of mechanisms, including inhibition of the magnesium-dependent enzyme Na^+/K^+-ATPase and increased activity of the Na^+/Ca^{2+} exchanger, thereby increasing intracellular calcium.	Separate drug and any magnesium supplements by at least 2 hours. Monitor magnesium status in patients taking digoxin.	(49, 50)
Diuretics (see Loop diuretics, Potassium-sparing diuretics, Thiazide diuretics)				
Doxorubicin (Adriamycin)	Riboflavin	Doxorubicin may inhibit the incorporation of riboflavin into active coenzyme, FAD, due to structural similarities.	Available data come from rodent models; human data are lacking. Separate drug and riboflavin intake by at least 4 hours to avoid any interaction; consider riboflavin supplementation.	(12, 51)
Doxycycline (Acticlate, Avidoxy, Doryx, Doryx MPC, Doxy 100, Mondoxyne NL, Morgidox, Oracea, Soloxide, Targadox, Vibramycin): see Tetracycline-class antibiotics				
Eplerenone (Inspra): see Potassium-sparing diuretics				
Eravacycline (Xerava): see Tetracycline-class antibiotics				
Esomeprazole (Esomep-EZS, GoodSense Esomeprazole [OTC], Nexium, Nexium 24HR [OTC], Nexium I.V.): see Proton-pump inhibitors				
Ethacrynic acid (Edecrin, Sodium Edecrin): see Loop diuretics				
Ethambutol (Myambutol)	Zinc	Ethambutol chelates zinc, which could prevent its absorption. This might increase the risk of zinc deficiency and associated visual impairments, including optic neuropathy.	Zinc supplementation may be needed, but long-term, excessive zinc supplementation can cause copper deficiency.	(52-54)
	Copper	Ethambutol chelates copper, but the exact MOA that leads to optic neuropathy is not known.	Separate drug and copper supplements by at least 2 hours. Due to the potential for ocular toxicity, it is prudent to closely monitor visual function, including changes in color vision.	(12, 52, 55)
Etidronate: see Bisphosphonates				
Famotidine (Acid Controller Max St [OTC], Acid Controller Original Str [OTC], Acid Reducer [OTC], Acid Reducer Maximum Strength [OTC], Famotidine Maximum Strength [OTC], Heartburn Relief [OTC], Heartburn Relief Max St [OTC], Heartburn Relief Max St [OTC], Pepcid, Pepcid AC Maximum Strength [OTC]): see Histamine-2 receptor antagonists				
Fluoroquinolone-class antibiotics (see Quinolone-class antibiotics)				
Fluorouracil (5-Fluorouracil)	Niacin	Use of 5-fluorouracil increases the reliance on dietary niacin by interfering with the tryptophan-kynurenine-niacin pathway, which converts tryptophan to nicotinamide adenine dinucleotide (NAD).	Oral niacin supplementation has been shown to relieve deficiency symptoms.	(56-58)
	Thiamin	5-Fluorouracil use may lead to thiamin deficiency as the drug inhibits the phosphorylation of thiamin to thiamin diphosphate/thiamin pyrophosphate, a required enzymatic cofactor in glucose and amino acid metabolism.		(59, 60)
Furosemide (Lasix): see Loop diuretics				
Histamine-2 (H_2) receptor antagonists (cimetidine [Cimetidine Acid Reducer [OTC], Tagamet, Tagamet HB], famotidine [Acid Controller Max St [OTC], Acid Controller Original Str [OTC], Acid Reducer [OTC], Acid Reducer Maximum Strength [OTC], Famotidine Maximum Strength [OTC], Heartburn Relief [OTC], Heartburn Relief Max St [OTC], Pepcid, Pepcid AC Maximum Strength [OTC]], nizatidine)	Vitamin B_{12}	Use of H_2 receptor antagonists may decrease the absorption of food-bound, but not supplemental, vitamin B_{12} due to decreased gastric acidity (gastric acid is needed to liberate the vitamin from proteins in food). Long-term drug use might result in vitamin B_{12} deficiency.	Monitor vitamin B_{12} status (buildup of methylmalonic acid), and consider vitamin B_{12} supplementation with long-term drug use.	(61, 62)
	Calcium	Decreased gastric acidity may impair release of ionized calcium from insoluble calcium salts (calcium carbonate and calcium phosphate), potentially decreasing its absorption in the upper small intestine.	Meet the RDA of calcium from dietary sources. If supplementation is needed, consider the calcium citrate form.	(63)
	Iron	Long-term use might decrease absorption of iron and thus decrease iron status, but this interaction may not be clinically significant.	Separate iron supplementation and drug use by at least 2 hours.	(64)
HMG-CoA reductase inhibitors (statins; atorvastatin [Lipitor], fluvastatin [Lescol XL], lovastatin [Altoprev], pitavastatin [Livalo, Zypitamag], pravastatin [Pravachol], rosuvastatin [Crestor, Ezallor Sprinkle], simvastatin [FloLipid, Zocor])	Nicotinic acid	Some case reports of co-administration of nicotinic acid with an HMG-CoA reductase inhibitor raise concern for an increased risk of myopathy and rhabdomyolysis; the mechanism is not known. Data from clinical trials are largely lacking, and it is not known whether the risk is higher than that associated with HMG-CoA reductase inhibitor monotherapy.	Patients should be aware of possible symptoms of myopathy and rhabdomyolysis and report any symptoms immediately to their healthcare provider.	(65, 66)
	Pantethine (metabolite of pantothenic acid)	Concomitant use of pantethine with any cholesterol-lowering drug may have additive effects on blood cholesterol.		(67, 68)
	Grapefruit	Grapefruit consumption inhibits intestinal CYP3A4 and may increase drug bioavailability and thus increase the risk of drug toxicity, especially HMG-CoA reductase inhibitors with low bioavailability (e.g., atorvastatin, lovastatin, and simvastatin).	Eliminate grapefruit from the diet in patients taking certain HMG-CoA reductase inhibitors, e.g., atorvastatin, lovastatin, or simvastatin. Alternatively, consider a statin that is not metabolized by CYP3A4, such as pravastatin or pitavastatin.	(69)
	Plant stanols or plant sterols	Concomitant use of plant stanols or sterols with any cholesterol-lowering drugs may have additive effects on blood cholesterol.		(70, 71)
Hydrochlorothiazide: see Thiazide diuretics				
Hydroflumethiazide: see Thiazide diuretics				
Ibandronate (Boniva): see Bisphosphonates				
Indapamide: see Thiazide diuretics				
Isoniazid	Niacin	Indirect interaction as the drug affects vitamin B_6-dependent enzymes (see Isoniazid and vitamin B_6). Vitamin B_6 is a cofactor for kynureninase in the tryptophan-kynurenine pathway that converts tryptophan to nicotinamide adenine dinucleotide (NAD); inhibition of kynureninase can lead to niacin deficiency.	Niacin supplementation may be needed during long-term isoniazid treatment.	(72-76)
	Vitamin B_6	Isoniazid may cause a functional vitamin B_6 deficiency, leading to peripheral neuropathy, by forming an inactive, covalently bound complex with pyridoxal 5'-phosphate (PLP). The drug has also been shown to inhibit select PLP-dependent enzymes.	Consider vitamin B_6 supplementation in those taking isoniazid to prevent peripheral neuropathy.	(46, 77, 78)
	Vitamin K	When taken by pregnant women, isoniazid might increase the risk of vitamin K deficiency and hemorrhagic disease of newborn infants. Only case reports are available; there are no data on MOA.	Report of possible interaction comes from two case reports where isoniazid, rifampicin, and ethambutol were all administered during pregnancy.	(79)
Ketoconazole	Vitamin D	Ketoconazole inhibits 25-hydroxyvitamin D_3-1α-hydroxylase, including the renal enzyme, and has been found to reduce serum 1α,25-hydroxyvitamin D (calcitriol) concentrations.	Monitor vitamin D status, including 1,25$(OH)_2$D concentrations, in patients taking oral ketoconazole.	(80-82)
Lansoprazole (GoodSense Lansoprazole [OTC], Heartburn Treatment 24 Hour [OTC], Prevacid, Prevacid SoluTab, Prevacid 24HR [OTC]): see Proton-pump inhibitors				
Levodopa with carbidopa (Duopa, Rytary, Sinemet)	Folate	Levodopa use may increase blood concentrations of homocysteine: levodopa methylation by catechol O-methyltransferase and S-adenosylmethionine produces S-adenosylhomocysteine, which is converted to homocysteine.	Adequate dietary folate intake and/or folic acid (and other B vitamin) supplementation may help decrease homocysteine concentrations in patients taking levodopa.	(83, 84)
	Vitamin B_6	Levodopa can form a covalent complex with pyridoxal 5'-phosphate and limit its bioavailability, creating a functional vitamin B_6 deficiency. High-dose pyridoxine supplementation has been found to decrease the efficacy of levodopa due to acceleration of levodopa-to-dopamine metabolism peripherally, thereby reducing availability of levodopa to the CNS.	Avoid vitamin B_6 supplementation with levodopa monotherapy. Co-administer levodopa with a dopamine decarboxylase inhibitor, such as carbidopa.	(15, 85-87)
	Iron	Levodopa/carbidopa may bind to iron and reduce absorption of both iron and the drug.	Separate drug and iron intake by at least 2 hours.	(88, 89)
Levothyroxine (Euthyrox, Levoxyl, Synthroid, Tirosint, Tirosint-SOL, Unithroid)	Calcium	Concomitant intake of levothyroxine and calcium supplements may decrease levothyroxine absorption, likely due to the formation of an insoluble complex. This interaction could decrease drug efficacy.	Separate levothyroxine and calcium supplementation by at least 4 hours. Preliminary evidence indicates that liquid levothyroxine might be less affected by concomitant mineral intake compared to tablet levothyroxine.	(90-93)
	Iron	Concomitant intake of levothyroxine and ferrous sulfate supplements may decrease the efficacy of levothyroxine, likely due to formation of an insoluble complex.	Separate levothyroxine and iron supplements by at least two hours. Preliminary evidence indicates that liquid levothyroxine might be less affected by concomitant mineral intake compared to tablet levothyroxine.	(93-95)
Lithium (Lithobid)	Iodide	Concomitant use of lithium and pharmacological doses of potassium iodide may increase the risk of hypothyroidism due to inhibition of thyroid hormone synthesis (i.e., Wolff-Chaikoff effect).	Monitor thyroid status in patients taking lithium.	(15, 96)
	Psyllium	According to a case report, psyllium supplementation may decrease lithium absorption. Psyllium seeds are rich in polysaccharides and may interfere with drug absorption.	Separate taking psyllium supplements and drug by at least 2 hours to avoid any possible interaction.	(15, 97)
Loop diuretics (bumetanide [Bumex], ethacrynic acid [Edecrin, Sodium Edecrin]; furosemide [Lasix], torsemide)	Magnesium	If taken for an extended period of time, high doses of loop diuretics can interfere with renal reabsorption of magnesium, increase urinary excretion of magnesium, and result in magnesium depletion.	Monitor magnesium status (dietary, serum, and urinary magnesium) in patients on long-term therapy with loop diuretics.	(98-100)
	Potassium	Use of loop diuretics can increase urinary excretion of potassium and may result in hypokalemia.		(101)
	Thiamin	By increasing urinary flow, loop diuretics (especially furosemide) may prevent renal reabsorption of thiamin, thereby increasing urinary excretion of thiamin and increasing risk of thiamin deficiency.	A daily multivitamin containing thiamin may help prevent deficiency.	(102-104)
Lymecycline: see Tetracycline-class antibiotics				
Metformin (Fortamet, Glucophage, Glucophage XR, Glumetza, Riomet, Riomet ER)	Vitamin B_{12}	Metformin interferes with ileal absorption of the intrinsic factor-vitamin B_{12} complex.	Monitor vitamin B_{12} status; measuring methylmalonic acid, in blood or urine, is a specific indicator of deficiency.	(105)
	Guar gum (Cyamopsis tetragonolobus)	When taken concurrently, guar gum may slow the absorption of metformin and decrease the amount absorbed.		(106)
Methyclothiazide: see Thiazide diuretics				
Methyldopa	Iron	Concomitant intake of methyldopa and ferrous sulfate or ferrous gluconate supplements may decrease the efficacy of methyldopa due to decreased intestinal drug absorption. MOA is unknown but postulated to be due to complex formation.	Separate drug and iron supplements by at least 4 hours.	(107, 108)
Methotrexate (Otrexup, Rasuvo, RediTrex, Trexall, Xatmep)	Folate	Methotrexate inhibits enzymes involved in nucleotide synthesis, including dihydrofolate reductase. Due to its antagonism, methotrexate use can lead to folate deficiency.	Supplementation with folic or folinic acid (leucovorin), which is recommended for patients with rheumatoid arthritis, reduces the antifolate toxicity.	(109-111)
Metolazone: see Thiazide diuretics				
Nitrous oxide	Vitamin B_{12}	Nitrous oxide oxidizes and inactivates vitamin B_{12}, thus inhibiting both of the vitamin B_{12}-dependent enzymes, methionine synthetase and L-methylmalonyl-coenzyme A mutase. This can produce many of the clinical features of vitamin B_{12} deficiency, including megaloblastic anemia and neuropathy.	Since nitrous oxide is commonly used for surgery in the elderly, consider ruling out vitamin B_{12} deficiency prior to its use.	(112, 113)
Nizatidine: see Histamine-2 receptor antagonists				
Olestra (Olean)	Fat-soluble vitamins	Olestra may sequester fat-soluble nutrients and cause impaired absorption of carotenoids and fat-soluble vitamins; vitamins A, D, E, and K may be added to olestra-containing foods for this reason.	The clinical significance of this interaction is not clear.	(114-116)
Omadacyclin (Nuzyra): see Tetracycline-class antibiotics				
Omeprazole (Acid Reducer [OTC], Prilosec, Prilosec OTC [OTC]): see Proton-pump inhibitors				
Orlistat (Alli [OTC], Xenical)	Fat-soluble vitamins	Orlistat may decrease the intestinal absorption of carotenoids and fat-soluble vitamins (vitamins A, D, E, and K).	Orlistat and vitamin supplements should be separated by at least 2 hours.	(117-121)
Oxytetracycline: see Tetracycline-class antibiotics				
Pamidronate: see Bisphosphonates				
Pantoprazole (Protonix): see Proton-pump inhibitors				
Penicillamine (Cuprimine, Depen Titratabs)	Vitamin B_6	Penicillamine may cause a functional vitamin B_6 deficiency by forming an inactive, thiazolidine complex with pyridoxal 5'-phosphate. This complex formation may also impair penicillamine action.	Supplemental pyridoxine has been used to prevent vitamin B_6 deficiency and may be considered in those with low vitamin B_6 status. Separating drug and supplement intake by at least 2 hours may help minimize the interaction.	(12, 122, 123)
	Copper	Penicillamine chelates copper and increases its urinary excretion.	It is generally advised that patients taking penicillamine to reduce copper status (e.g., in Wilson's disease) limit copper intake from food and avoid any copper-containing supplements.	(12)
	Iron	Penicillamine chelates iron and increases its excretion. Concomitant intake of penicillamine and iron supplements decreases drug absorption and efficacy. Discontinuation of oral iron supplements while on penicillamine therapy has been associated with glomerulonephritis, presumably due to increased drug absorption and toxicity.	Separate drug and iron supplements by at least 2 hours.	(124, 125)
	Magnesium	Magnesium and penicillamine may complex together and prevent intestinal absorption of both magnesium and the drug.	Separate drug and magnesium supplements or magnesium-containing antacids by at least 2 hours. Assess magnesium status before high-dose penicillamine.	(12, 124)
	Zinc	Penicillamine is a metal chelator, and its use may reduce intestinal absorption of zinc and increase its excretion, increasing risk of zinc deficiency. Use of zinc supplements may decrease the absorption of penicillamine.	Separate drug and zinc supplements by at least 2 hours. Closely monitor patients as zinc supplementation can reduce copper status through inhibiting copper absorption and increasing copper excretion.	(12, 126)
Phenytoin (Dilantin, Dilantin Infatabs, Phenytek)	Folate	Phenytoin inhibits the intestinal absorption of folate and lowers serum folate concentrations. Supplementation with high-dose folic acid may lead to decreased serum concentrations of phenytoin.	Long-term phenytoin use may decrease folate status. Folic acid supplementation is often recommended when beginning phenytoin. Closely monitor serum concentrations of phenytoin.	(127-129)
	Thiamin	Lower blood concentrations of thiamin have been reported in those taking phenytoin for epilepsy. MOA is not known.	Research is limited. Monitor thiamin status and consider thiamin supplementation if necessary.	(130, 131)
	Vitamin B_6	Extremely high dosages of pyridoxine (≥80 mg/day) have been associated with decreased phenytoin concentrations in patients taking multiple anticonvulsants for epilepsy. MOA is not known.	Avoid high doses of pyridoxine.	(132)
	Vitamin D	Phenytoin use has resulted in decreased serum concentrations of 25-hydroxyvitamin D, perhaps due to increased metabolism of vitamin D to inactive metabolites in the liver.	Long-term phenytoin use may require vitamin D and calcium supplementation to prevent deleterious effects on bone health.	(133-135)
	Vitamin K	Phenytoin may increase the risk of vitamin K deficiency and hemorrhagic disease of newborn infants when taken by pregnancy women. MOA hypothesized to include induction of fetal hepatic enzymes that increase oxidative degradation of vitamin K.	Hemorrhagic disease of the newborn may be more serious in newborns of women treated with anticonvulsants. Vitamin K is administered to newborns immediately after birth to prevent hemorrhagic disease.	(136)
	Piperine (in some curcumin supplements)	Piperine may increase the bioavailability and slow the elimination of phenytoin through interfering with efflux drug transporters and phase I cytochrome P450 enzymes.	Data on an interaction are limited.	(137, 138)
Polythiazide (Renese): see Thiazide diuretics				
Potassium-sparing diuretics (amiloride, eplerenone [Inspra], spironolactone [Aldactone, CaroSpir], triamterene [Dyrenium])	Folate	Triamterene impairs intestinal absorption of folate and inhibits dihydrofolate reductase, which converts dihydrofolate to the active form of folate, tetrahydrofolate.	Encourage patients on long-term triamterene therapy to consume the RDA for folate through diet and/or supplements. Measuring folate concentrations in red blood cells is a better indicator of folate status than serum folate concentrations.	(109, 139)
	Phosphate	If taken with phosphate supplements, potassium-sparing diuretics may result in hyperkalemia.	Be aware of the potential interaction and of supplement intake by patients.	(16)
	Zinc	Some, but not all, studies have found that amiloride use decreases urinary excretion of zinc – the effect may depend on drug dosage. One small study found no effect of triamterene on urinary excretion of zinc.	Amiloride has been used in combination with thiazide diuretics to mitigate the risk of zinc depletion.	(140-142)
Proton-pump inhibitors (dexlansoprazole [Dexilant], esomeprazole [Esomep-EZS, GoodSense Esomeprazole [OTC], Nexium, Nexium 24HR Clear Minis [OTC], Nexium 24HR [OTC], Nexium I.V.], lansoprazole [GoodSense Lansoprazole [OTC], Heartburn Treatment 24 Hour [OTC], Prevacid, Prevacid 24HR [OTC], Prevacid SoluTab], omeprazole [Acid Reducer [OTC], Prilosec, Prilosec [OTC]], pantoprazole [Protonix], rabeprazole [Aciphex, AcipHex Sprinkle])	Vitamin B_{12}	Use of proton-pump inhibitors may decrease the absorption of food-bound, but not supplemental, vitamin B_{12} due to decreased gastric acidity (gastric acid is needed to liberate the vitamin from proteins in food). Long-term drug use can result in vitamin B_{12} deficiency.	Monitor vitamin B_{12} status (buildup of methylmalonic acid), and consider vitamin B_{12} supplementation with long-term drug use.	(143, 144)
	Calcium	Decreased gastric acidity may impair release of ionized calcium from insoluble calcium salts (calcium carbonate and calcium phosphate), potentially decreasing its absorption in the upper small intestine.	Meet the RDA of calcium from dietary sources. If supplementation is needed, consider the calcium citrate form.	(63)
	Iron	Long-term use of proton-pump inhibitors might decrease intestinal absorption of iron and iron status, but this interaction may not be clinically significant.	Separate iron supplementation and drug use by at least 2 hours.	(64)
	Phosphate	A reduction in stomach acidity may limit efficacy of oral phosphate-binder therapy in patients with kidney failure.		(145)
Pyrimethamine (Daraprim)	Folate	Pyrimethamine has been shown to competitively inhibit dihydrofolate reductase. Supplemental folic acid may interfere with the antitoxoplasmic effect of the drug, sulfadoxine/pyrimethamine.	Consider supplemental folinic acid.	(146, 147)
Quinolone-class antibiotics (ciprofloxacin [Cipro]; gemifloxacin; levofloxacin; lomefloxacin [Maxaquin]; moxifloxacin; ofloxacin)	Calcium	Concomitant administration of calcium supplements and quinolone antibiotics may decrease both antibiotic and mineral absorption, presumably due to formation of nonabsorbable chelates in the intestine.	Separate antibiotic dose by 2 hours before or 6 hours after calcium intake from food (including calcium-fortified foods) and supplements, or from calcium-containing drugs (e.g., antacids).	(148-152)
	Iron	Concomitant administration of ferrous sulfate supplements and quinolone antibiotics may decrease both antibiotic and mineral absorption, presumably due to formation of nonabsorbable chelates in the intestine.	Separate antibiotic dose by 2 hours before or 6 hours after iron intake from food or supplements.	(12, 153, 154)
	Magnesium	Concomitant administration of magnesium supplements and quinolone antibiotics might decrease both antibiotic and mineral absorption, presumably due to formation of nonabsorbable chelates in the intestine.	Studies are lacking, but an interaction may occur given the reported interaction with magnesium-containing antacids and ciprofloxacin, although the antacids studied also contained aluminum hydroxide. Prudent to separate antibiotic dose by 2 hours before or 6 hours after magnesium supplements.	(155-157)
	Zinc	Concomitant administration of zinc supplements and quinolone antibiotics might decrease both antibiotic and mineral absorption, presumably due to formation of nonabsorbable chelates in the intestine.	Research is limited. Separating antibiotic dose by 2 hours before or 6 hours after zinc intake from food or supplements would help minimize any interaction.	(154)
Rabeprazole (Aciphex, AcipHex Sprinkle): see Proton-pump inhibitors				
Rifampin/Rifampicin (Rifadin)	Vitamin D	Rifampin may increase the metabolism of vitamin D to inactive metabolites by induction of liver enzymes, thereby decreasing serum concentrations of 25-hydroxyvitamin D.	Vitamin D supplementation may be needed.	(158)
	Vitamin K	When taken by pregnant women, rifampin might increase the risk of vitamin K deficiency and hemorrhagic disease of newborn infants. Only case reports; there are no data on MOA.	Report of possible interaction comes from two case reports where isoniazid, rifampicin, and ethambutol were all administered during pregnancy.	(79)
Risedronate (Actonel, Atelvia): see Bisphosphonates				
Sarecycline (Seysara): see Tetracycline-class antibiotics				
Spironolactone (Aldactone, CaroSpir): see Potassium-sparing diuretics				
Sulfasalazine (Azulfidine, Azulfidine EN-tabs)	Folate	Sulfasalazine is a folate antagonist that can inhibit the reduced folate carrier and the proton-coupled folate transporter, decreasing intestinal absorption of folate.	Monitor folate status and consider supplemental folic acid if needed. Separating drug and folate intake may help prevent an interaction.	(159, 160)
Tetracycline-class antibiotics (chlortetracycline, demeclocycline, doxycycline [Acticlate, Avidoxy, Doryx, Doryx MPC, Doxy 100, Mondoxyne NL, Morgidox, Oracea, Soloxide, Targadox, Vibramycin], eravacycline [Xerava], lymecycline; omadacyclin [Nuzyra], oxytetracycline, sarecycline [Seysara], tetracycline)	Calcium	Calcium from food (e.g., milk) or supplements may decrease absorption of the antibiotic due to chelate formation in the intestine; absorption of calcium may also be decreased.	Separate antibiotic dose by 2 hours before or 6 hours after calcium intake from food or supplements.	(161, 162)
	Iron	Iron from food or supplements may decrease absorption of the antibiotic due to chelate formation in the intestine; absorption of iron may also be decreased.	Separate iron supplements from antibiotics by at least 2 hours.	(15, 162)
	Magnesium	Concomitant intake may decrease both drug and mineral absorption due to chelate formation in the intestine.	Separate antibiotic dose from magnesium-rich food or supplements by 2 hours or 4-6 hours after magnesium.	(15)
	Manganese	Concomitant intake may decrease manganese absorption due to complex formation in the intestine.		(15)
	Zinc	Concomitant intake may decrease both drug and mineral absorption due to chelate formation in the intestine. One small, cross-over study found that zinc sulfate did not inhibit absorption of doxycycline.	Separate antibiotic dose from zinc supplements by at least 2 hours.	(15, 161, 163, 164)
Thiazide diuretics (nadolol/bendroflumethiazide, chlorothiazide [Diuril, Sodium Diuril], chlorthalidone [Hygroton, Thalitone], hydrochlorothiazide, hydroflumethiazide, indapamide, methyclothiazide, metolazone)	Calcium	Thiazide diuretics increase renal reabsorption of calcium and thus decrease its excretion.	If taken in combination with calcium supplements, thiazide diuretics may increase the risk of hypercalcemia.	(165)
	Magnesium	If taken for an extended period of time, high dosages of thiazide diuretics can interfere with renal reabsorption of magnesium, increase urinary excretion of magnesium, and result in magnesium depletion.	Monitor magnesium status (dietary, serum, and urinary magnesium) in patients on long-term therapy with thiazide diuretics.	(98-100)
	Potassium	Thiazide diuretics increase urinary excretion of potassium in a dose-dependent manner; their use may result in potassium depletion.	Monitor serum potassium concentrations in patients taking thiazide diuretics.	(166)
	Zinc	Thiazide diuretic use may inhibit zinc reabsorption in the distal tubule of the kidneys and thus increase urinary excretion of zinc, possibly decreasing zinc status.	Prolonged use of thiazide diuretics may increase risk of zinc depletion.	(142, 167, 168)
Torsemide: see Loop diuretics				
Trimethoprim (Primsol); Trimethoprim-sulfamethoxazole (Bactrim, Bactrim DS, Sulfatrim Pediatric)	Folate	Trimethoprim inhibits dihydrofolate reductase, which converts dihydrofolate to the active form of folate, tetrahydrofolate. Sulfamethoxazole inhibits bacterial production of dihydropteroate. Use of trimethoprim or trimethoprim-sulfamethoxazole may thus increase the risk of folate deficiency.	Inhibition of the bacterial enzyme by trimethoprim is thousands-fold more efficient than the mammalian enzyme; risk of folate deficiency increases with higher dosages of trimethoprim, especially when administered for prolonged periods. Measuring folate concentrations in red blood cells is a better indicator of folate status than serum folate concentrations. Supplementation with folinic acid (leucovorin) may reduce the antifolate toxicity.	(12, 169-172)
Valproic acid (Depakote, Depakote ER, Depakote Sprinkles)	Carnitine	Valproic acid may decrease carnitine status and lead to deficiency if the drug is taken for a prolonged period of time. Valproic acid interferes with L-carnitine biosynthesis in the liver and forms with L-carnitine a valproylcarnitine ester that is excreted in the urine.	L-carnitine supplements may be necessary in a subset of patients taking valproic acid. Risk factors for L-carnitine deficiency with valproic acid include young age (<2 years), severe neurological problems, use of multiple antiepileptic drugs, poor nutrition, and consumption of a ketogenic diet.	(173-175)
Verapamil (Calan SR, Verelan, Verelan PM)	Calcium	Calcium may decrease the hypotensive effect of intravenously provided verapamil.		(176)
Warfarin (Jantoven)	Vitamin C	Some evidence from case reports indicate that large oral doses might inhibit the action of warfarin.	Limit vitamin C intake from supplements to 1 g/day and monitor prothrombin time/INR.	(177, 178)
	Vitamin E	High-dose supplementation with vitamin E may inhibit vitamin K-dependent carboxylase activity, thus interfering with the coagulation cascade.	Evaluate use of vitamin E supplements due to an increased risk of bleeding.	(179)
	Vitamin K	Warfarin prevents recycling of vitamin K by antagonizing the enzyme, vitamin K oxidoreductase, thereby creating a functional vitamin K deficiency. Low dietary intakes of vitamin K can cause an unstable INR, and very high dietary (>150 µg/day) or supplemental intake of vitamin K may compromise the anticoagulant effect of warfarin.	It is generally recommended that individuals using warfarin try to consume the adequate intake for vitamin K (90 µg/day for women and 120 µg/day for men) and avoid large fluctuations in vitamin K intake that might interfere with the adjustment of their anticoagulant dose.	(180, 181)
	Boldo (*Peumus boldus*)-fenugreek (*Trigonella foenum-graecum*)	One case report of increased INR with co-supplementation of boldo and fenugreek while on warfarin therapy. MOA is not known. An active compound in boldo, baldine, inhibited aggregation of rabbit platelets *in vitro*. Fenugreek reportedly contains coumarin derivatives.	Interaction has been rated as 'highly probable' (182).	(183-185)
	Chitosan (*Swertia chirayita*)	Case report of increased INR with chitosan supplementation. MOA is unknown, although the authors of the case report state impaired absorption of vitamin K may be likely.	Monitor INR in those taking chitosan. Clinical studies are needed to determine if there is an interaction.	(186)
	Coenzyme Q_{10}	Coenzyme Q_{10} and forms of vitamin K are structurally similar.	Avoid coenzyme Q_{10} supplements in patients taking warfarin due to increased risk of blood clotting. If concomitantly used, assess prothrombin time/INR frequently, especially in the first two weeks.	(187)
	Cranberry juice	An increased INR has been documented in case reports (MOA not clearly explored), but no interaction has been found in controlled studies.	Monitor INR if patients consume cranberry juice.	(188-192)
	Danshen (*Salvia miltiorrhiza* root)	Case reports of increased INR and prothrombin time, possibly through effects on CYP450 enzymes. Results of a rat study indicate tanshinone IIA, a bioactive compound of danshen, binds to albumin and displaces warfarin, thus increasing blood concentration of warfarin and its effect. Inhibition of warfarin hydroxylation has also been shown in one rat study.	Avoid supplementation with herb.	(193-197)
	Compound Danshen Dripping Pill (CDDP; *Salvia miltiorrhiza*, borneol, and tanshinol)	A clinical study in patients with coronary heart disease with atrial fibrillation found CDDP had no effect on warfarin pharmacokinetics or pharmacodynamics.		(198)
	Devil's claw (*Harpagophytum procumbens*)	Report of purpura with co-administration of warfarin and devil's claw.	Little information is available in the published literature.	(199)
	Dong quai (*Angelica sinensis*)	Case report of increased INR with co-administration with warfarin. The herb contains coumarin derivatives.	Interaction has been rated as 'probable' (182).	(200)
	Echinacea	One small study in healthy men found co-treatment with echinacea and warfarin increased clearance and decreased plasma concentrations of (S)-warfarin, but did not affect INR or platelet aggregation. In a small, open-label study, echinacea had no effect on the metabolism of tolbutamide, which, like S-warfarin, is metabolized by CYP2C9.	Clinical studies are needed to determine if there is an interaction.	(188, 201)
	Fish oil	One case report of an interaction, but more recent studies have found no effect of fish oil supplementation on coagulation measures or bleeding incidence when co-administered with warfarin.	Monitor INR in patients taking fish oil.	(202, 203)
	Garlic	Garlic might enhance the anticoagulant effects of warfarin because of its antiplatelet properties. While two case reports have raised concern, clinical trials have found no adverse effects.	More research is needed to determine whether they are safe in patients on anticoagulant therapy. Closely monitor INR in patients taking garlic supplements.	(188, 204-206)
	Ginger	Case reports have suggested an interaction of high-dose ginger supplementation with warfarin. An open-label, cross-over study found no effect of ginger supplementation on platelet aggregation or INR in healthy individuals who were administered only a single dose of racemic warfarin (25 mg).	Clinical studies are needed to determine if there is an interaction.	(207-209)
	Ginkgo biloba	Several case reports of spontaneous bleeding with the use of the herb alone, but a meta-analysis of randomized controlled trials found no increased risk. Cross-over trials of its use with warfarin found no effects on INR and the pharmacokinetics or pharmacodynamics of warfarin or on INR.	Monitor INR if patients on warfarin are taking ginkgo extracts or supplements.	(209-212)
	Ginseng	One case report of decreased INR with ginseng supplementation (Ginsana, 3 times per day; dose not stated). One clinical study found American ginseng decreased INR after two weeks' supplementation. Other clinical studies have found no effect of Korean ginseng root or Korean red ginseng on INR, warfarin pharmacokinetics, or warfarin pharmacodynamics.	More research is needed. Monitor INR if patients on warfarin take ginseng supplements.	(213-216)
	Grapefruit	One case report of a possible interaction; a small clinical study found no effect of grapefruit juice on prothrombin time or INR.	Clinical studies are needed to evaluate whether there is an interaction.	(217, 218)
	Green tea	Green tea is a source of vitamin K. Consumption of large amounts of green tea could decrease INR.	Avoid large amounts (>0.5L per day) of green tea. Patients taking warfarin should have consistent dietary intake of vitamin K intake and avoid large fluctuations.	(219)
	Mango	Case report of 13 older men with increased INR following mango consumption. MOA is not known but hypothesized to include inhibition of CYP2C19 by vitamin A.	Interaction has been rated as 'highly probable' (182).	(220, 221)
	Papain from papaya	Papain intake may increase INR, e.g., may increase bleeding by harming the integrity of the mucosal membranes of	Only one case report. Avoid supplementation with papaya extract; encourage eating fresh papaya instead.	(199)

		integrity of the mucosal membranes of the GI tract. However, the exact mechanism is unknown.		
	Pomegranate (*Punica granatum*)	One case report of increased INR with high intake of pomegranate juice. Pomegranate juice has been found to inhibit CYP2C9 activity *in vitro*.	Clinical studies are needed to evaluate whether there is an interaction.	(222, 223)
	Psyllium (*Plantago ovata*)	Psyllium supplements may slow and decrease intestinal absorption of warfarin if taken concomitantly.	Separate taking psyllium supplements and drug by at least 2 hours.	(15)
	Resveratrol	Resveratrol inhibits platelet aggregation *in vitro*.	Supplemental intake could theoretically increase the risk of bruising and bleeding when taken with warfarin.	(224, 225)
	Soy protein	One case report of a decreased INR in a patient taking warfarin following consumption of soy milk. MOA is unknown.	Monitor INR if the patient adds or eliminates soy protein from diet.	(226)
	St. John's wort (*Hypericum perforatum*)	Use of St. John's wort has been shown to induce various CYP450 enzymes, increasing warfarin clearance and decreasing INR.	Closely monitor INR.	(216)
	Sweet clover	Interaction might be possible since the herb contains coumarin derivatives.	Human reports are lacking.	(227)
	Turmeric (*Curcuma longa*)	Curcumin from turmeric has been found to inhibit platelet aggregation *in vitro*, thus curcumin supplementation could theoretically affect risk of bleeding in patients taking warfarin. A small pilot study found no effect of the curcumin formulation, Meriva®, on INR.	Clinical research is needed to determine whether curcumin supplementation interacts with warfarin.	(228, 229)
Zoledronic acid (Reclast): see Bisphosphonates				
US brand names listed in parentheses. *Abbreviations: INR, international normalized ratio; MOA, mechanism of action*
